SUPPLEMENT TO "THE ELECTRICIAN," MAY 11, 1888.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

VOLUME XX.

FROM NOVEMBER 11, 1887, TO MAY 4, 1888.

LONDON:
Printed and Published for the Proprietors by GEORGE TUCKER, at "THE ELECTRICIAN" Offices, 1, Salisbury-court, Fleet-street, E.C.

1888.

Digitized by Google

INDEX TO "THE ELECTRICIAN."

VOL. XX.

Leading Articles and Editorial Notes.

(In this Section LEADING ARTICLES are shown in Capitals.)

Accumulators, Mr. R. E. B. Crompton on, 727.
Acheson's Cal-Electric Generator, 279.
Admiralty Specification for Engines and Dynamos, 559.
Alarm Telegraphs, 463.
Alternate-Current Machines, Mr. Swinburne's Adjustment of, 682.
Alternate-Current Phases, 431.
Alternating v. Battery Transformers, 618.
Alternating-Current Electrolysis, 123
AMERICAN BELL TELEPHONE SUIT, THE, 598.
American Bell Telephone Company, The, 585, 618.
American Criticism, An, 585.
American Electric Light Association, The, 495.
Anglo-American Brush Corporation v. Crompton and Co. (Limited), 47.
Anglo-American Brush Corporation, The Report of the, 464.
Arc Light for Shops 500.
Association of Edison Companies, The Meeting of the, 464.
Association of Electrical Engineers, Proposed, 559.
ATLANTIC CABLE RATES, THE, 382.
Ayrton and Perry's Voltmeter, 69.
BANQUET, THE SIR JOHN PENDER, 704.
Battery Distribution, 465.
Battery v. Alternate-Current Transformers, 431.
Bell Telephone Patent, The, 527.
Bell v. Drawbaugh, 585.
Benardos', Dr., System of Electric Welding, 45.
BLACKPOOL, THE ELECTRIC LIGHT AND TRAMWAYS AT, 10.
Blackpool Electric Tramway, The, 95.
Blizzard in New York, The, 495.
Board of Trade, Interference of the, 559.
BRADFORD CORPORATION, THE, AND THE ELECTRIC LIGHT, 158.
Brighton Central Station, The, 147, 173.
Brussels Exhibition, The, 71.
CABLE OPERATIONS IN 1887, 265.
Capital Punishment by Electricity, 281, 307.
Chancellor of the Exchequer, The, and the Post Office, 2.
China, Telegraphs in, 682.
Coefficients of Self-Induction, Variation of the, 682.
Condensers and Alternating Currents, 24, 45.
County Government Bill, The, and the Electric Light, 527.
CRAWFORD'S, LORD, BILL, 662.
DEFENCES, OUR ELECTRICAL, 540.
Delany Multiplex Telegraph, The, 617.
Dielectric, Stress and Strain in the, 560.
Direct v. Alternating Currents, 46.
DISTRIBUTION OF POWER, THE, 106.
Dynamos with Cast-iron Magnets, 147.
Edison and Swan v. Anglo-American Brush Corporation, 649.
Edison Lamp, The New, 465.
Edison Meter, The, 174.
Edison System in America, 464.
Electric Dog-Cart, Volk's, 199.
ELECTRIC LIGHT AMENDMENT BILL, PROSPECTS OF THE, 476.
ELECTRIC LIGHT, THE, AND THE CITY, 414.
ELECTRIC LIGHT AND POWER INDUSTRIES IN 1887, THE, 210.
Electric Light, The Inventor of the, 727.
Electric Lighting Bill, The, 464, 495.
Electric Power Circuits, 560.
Electric Sunstroke, 254, 279.
ELECTRIC TRACTION ON THE UNDERGROUND RAILWAY, 705.
ELECTRICAL ENGINEERS, THE TRAINING OF, 54.
Electrical Engineers, Proposed Association of, 1.
Electrical Type-Writer, Higgins', 148.
Electricity and Earthquakes, 433.
Electricity Applied to Pumping in Mines, 560.
Electropathic Belts, 24.
Electro-Physiology, 254.
Electro-Static Experiments, 496.
Elwell-Parker Motors on the Blackpool Tramway, 95.
Ferranti v. Gaulard-Gibbs, 1.
Fire Office Rules, 527, 561, 586.
Fire Risks, Rules of the Society of Telegraph-Engineers, 617.
Forbes Meter, The, 174.
GOVERNMENT, THE, AND THE CHANNEL CABLES, 32.
Government Control, A Disadvantage of, 727.
Holmes-Burke, The, Cell, 46.
House-to-House Company, The, 432.
Imperial Continental Gas Association and the Incandescent Lamps, Effects of Currents on, 1, 432.
Incandescent Lamps and High Candle-Power, 400.
Incandescent Lamps, Maximum Efficiency of, 728.
Institute of Medical Electricity, The, 225.
Insulation, Remarkable, 333.
INVENTORS AND PROMOTERS 80.
Irish's India-Rubber Conduit, 199.
Japan, Telegraphs in, 682.
John Pender, Banquet to Sir, 728.
Large Voltmeter, A, 70.
Leamington Central Station, The, 25.
Liepmann Battery, The, 24.
"LIGHTNING AND THUNDERBOLTS," 570.
Lightning Conductors Dr. Oliver Lodge on, 496, 528.
Lightning Conductors, Prof. Silvanus Thompson on, 308.
LIGHTSHIPS AND THE TELEGRAPH, 746.
Long-Distance Telephony, 309.
Magnetic and Electric Induction, 121.
Magnetic Lag, 431.
Magnetic Resistance, 587.
Manganese Steel, Specific Resistance of, 463.
Maxim-Weston Company, The, 561, 681.
Meteorological Society, The Exhibition of the, 495.
Mordey Transformer Experiment, 463.
Motor Generator, The, 95.
Motor Generators, 618.
New Electric Club House in New York, Opening of 368.
New Force, Dr. Shettle's Supposed, 122.
New Voltmeter, A, 70.
O'Keenan Battery, The, 496.
Overhead Wires, 431.
PARLIAMENT AND THE ELECTRIC LIGHT, 348.
Patten Dynamo, The, 121.
Pilsen-Joel Electric Light Company, The, 650.
Platinum Wire, "Catalytic" Powers of, 253.
Portable Reflecting Galvanometer, Addenbrooke's, 496.
POSTMASTER-GENERAL, THE, AND THE TELEPHONES, 318.
POST OFFICE TELEGRAPHS IN 1887, 264.
Post Office Telegraphs, 528.
Priestman Engine, The, 728.
Primary Batteries, Mr. Perry F. Nursey on, 2.
Primary Batteries, Residual Products of, 2
Pyro-Magnetic Generator, A, 45.
Radiograph, The, 617.
Rendering Current Phases Visible, 333.
Reversible Battery Cases, 174.
Robertson Writing Telegraph, 560.
St. James's and Pall Mall Electric Light Co., The, 650.
Schanschieff Battery, The, 559.
SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS, THE, 132.
Society of Telegraph-Engineers and Electricians, Title of, 4 .
Society of Telegraph-Engineers and Electricians, The Committee of the, 586.
Society of Telegraph-Engineers and Electricians, The, New Title of, 334
SOUTH KENSINGTON, 639.
Storage Battery Traction, 70.
Submarine Mining, 463.
Submarine Telegraph Company, The, and the Government, 367.
Submarine Telegraph Company, The, and the Post Office, 2
Technical Schools, 69.
TELEGRAPHS OF THE EMPIRE, THE, 508.
TELEGRAPH, THE, IN AMERICA, 184.
TELEPHONE, THE, IN 1887, 238, 265.
Telephonic Communication at Sea, 95.
Telephone Companies, The Amalgamation of the, 585.
Telephone Companies, The Postmaster-General and the, 455.
Telephone Dispute, Prof. Silvanus Thompson on the, 1.
Telephones, Government Purchase of the, 495.
Telephone Rates and Renters, 122.
Thermo-Magnetic Experiments, Gore's, 254.
Thermo-Magnetic Experiments, Hinghausen and Nernst, 280.
Thermo-Magnetic Machines, 96.
Thermo-Magnetic Motor, Menges', 226.
Thurlow's, Lord, Bill, 681.
Trade Catalogue Piracy, 561.
TRANSFORMERS, THE BATTLE OF THE, 446.
Transformers, Gisbert Kapp on, 333.
Transformers, Kenneth D. Mackenzie, 367.
Transformers v. Accumulators, 70.
Transformers Worked in Series, 399.
Unequal Sparking in a Two-Pole Dynamo, 96
United Telephone Company v. Equitable Telephone Company, 527.
Wind Power, Utilisation of, 464.
WORLD'S ELECTRIC INDUSTRY, THE, 292.

Foreign Correspondence.

AMERICAN LETTER.

Alternating Currents, Curious Fact connected with, 519.
American Bell Telephone Company, Annual Meeting of, 642.
Apparatus for Protecting Linesmen, 660.
Association of Edison Companies, The Meeting of the, 449.
Bell Patent Decision, 610.
Blizzard in New York, The, 578.
Boston Electric Exchange, 718.
Cabling Extraordinary, 114.
Capital Punishment by Electricity, 326, 760.
Chinese Telephone Concessions, 141.
Edison's Improved Phonograph, 578.
Edison Litigation, 660.
Edison Phonograph, A Modification of, 240.
Edison Station in New York, A New, 141.
Eichmeyer Ironclad Dynamo, The, 241.
Electric Light Accidents, 760.
Electric Light, The, and the Gas Companies, 759.
Electric Motors, Novel Uses for, 358.
Electric Railroads, Prospects of, 760.
Electric Railway, The Allegheny City, 416.
Electric Railway, The Richmond Va., 415.
Electric Railways in New York, The Proposed, 388.
Electric Tramways, 245.
Electrical Exhibition at New York, 114.
Electrical Police Alarm, The, 222.
Electrical Subway, Accident in the New York, 358.
Electrical Subways in America, 759.
Electrical Subways, The New York, 114, 222.
Fourth Avenue Electric Tramway, 551.
French Cable Company, Decision against the, 326.
High-Tension Dynamo, A, 578.
Incandescent Lamps, Efficiency of, 720.
Induction Systems of Electric Lighting, 241.
Keely Motor, The, 719
Large Switch-board, A, 244.
Lighting Buoys by Electricity, 244.
Meserole Secondary Battery, The, 245.
Method of Regulating Three-Wire System, Elihu Thomson's, 241.
Mexico, Electric Light in, 416.
Morrison, Mr. J. F., 209.
Monster Memorial by the Knights of Labour, 326
National Electric Light Association of Pittsburg, Meeting of the, 518.
New Electric Club House in New York, The, Opening of, 389.
Niagara and the Electric Light, 389.
Niagara, Utilising, 719.
Non-Magnetic Watches, 388.
Patent Law Bill, 719.
Phonograph Improvements, 240.
Phonographs and Graphophones, 660.
Postal-Telegraph Schemes, Development of, 550.
St. Louis Telephone Company, 358.
Silicon-Bronze Wire, 142.
Sprague Company, Important Contract of the, 519.
Storage Batteries in Central Stations, 300.
Sugar Refining by Electricity, 358.
Telautograph, Prof. Elisha Gray's, 643.
Telephone Improvements, 240
Telephone Rates in New York, 760.
Telephonic Development in Nova Scotia, 166.
Teleseme System in New York, 551.
Thermo-Electricity, Developments in, 245.
Train Telegraph Apparatus, 240.
Transformers, Mr. Leonard on, 578.
United States Government, The, and the Telegraphs, 357.
Water-Power and Electricity, 271.
Westinghouse Company, Remarkable Progress of, 142, 166, 221.

BERLIN LETTER.

Electric Lighting Progress in Germany, 551.

BRUSSELS LETTER.

Brussels Exhibition, The Electric Light at 451.
Central Stations in Belgium, 450.

PARIS LETTER.

International Exhibition of 1889, The Lighting of the, 520.
Municipal Council, The, and the Electric Light, 519, 611.

STOCKHOLM LETTER.

Swedish Government, The, and the Telephones, 759.
Central Station at Vesteras, 760.
Incandescent Lamp Factory at Stockholm, 760.
Porsgrund, Installation at, 388.
Telephones and Telegraphs in Scandinavia, 579.

Original Papers, Translations, &c.

(In this Section ORIGINAL COMMUNICATIONS are shown with an asterisk.)

*Alternate Currents, Notes on, 28, 235, 285, 314, 404, 502, 590, 654, 734. — FLEMING, J. A.
*Ammeters and Voltmeters, Paterson and Cooper's, 229.
*Amsterdam, The Electric Light at, 537.
*Balances, Standardising Sir William Thomson's, 353.
Benardos' Method of Electric Welding, 58. — RUHLMANN, Dr. R.
*Cable Steamship "Amber," The New, 266, 747.
Cable Testing—The False Zero Method, 316. — LACOINE, EMILE.
Calibration of Galvanometers, Elementary Note on the, 181.
Central Station Indicating Instruments of the Edison Company, 266, 293.
Conductivity of Amalgams, The, 79. — WEBER, C. L.
*Conductors, Numbering, 507.
*Continuous-Current Transformation, 623, 733. — SELLON, R. P.
*Continuous-Current Transformers, Jehl and Rupp's System of, 7.
*Current Densities, Table of, 138.
*Current Indicator for Arc-Light Circuits, 180.
*Cut-Out, Magnetic, Cunynghame, Woodhouse and Rawson's, 670.
Cuttriss's Improved Siphon Recorder, 8.
Desmazures Secondary Battery, The, 13. — REYNICK, M. E.
Dimensions of the Magnetic Quantities in C.-G.-S. Units (Electro-Magnetic Measures), On the, 163. — HOSPITALIER, M. E.
Distribution by Direct Currents and by Transformers, Comparative Cost of, 286. — STANLEY, Mr.
*Dog Cart, Volk's Electric, for Ordinary Roads, 216.
DYNAMOS:—
*Blakey-Emmott, The, 35.
*Fowler-Lancaster, The, 538.
*Kennedy's Single-Magnet, 217.
*Paris and Scott's New, 161.
*Paterson and Cooper's, 567.
Patten Double-Rotation, The, 133.
*Electrical Appliances Used with Torpedoes and Submarine Mines, 469, 501. — M'EVOY, Capt. C. A.
*Electrical Power Storage Company's New Type of Cell, The, 221.
*Electric Lighting Experiences in India, 216. — DAVIES, L. A.
*Electric Wave and Phase Indicator for Alternating and Undulatory Currents, 350. — THOMSON, E.
Electrolysis of Iron Salts, 6, 50, 135, 156, 185, 241. — WATT, ALEXANDER.
*Electro-Magnetic Induction and its Propagation (conclusion), 189. — HEAVISIDE, OLIVER.
*"Excess" Alarms for Secondary Batteries, 62.
*Experiments on the Conditions which Determine the Stability of a Telegraph Wire, 373, 406. — CAWS, F.
Fire-Alarm, Automatic, Detnisienski's, 568.
*Frankfurt-Offenbach Electric Tramway, The, 532. — KRAUSE, E.
Glass Condenser, On a, 644. — LEHMANN, E.
*High Resistance Metals and Alloys, 564. — MORDEY, W. M.
Incandescent Lamp Filaments, The Size of, 633. — HOSPITALIER & HENRIQUE, MM.
*Incandescent Lamp Manufacture—Amyloid Carbons, 156, 180. — CHERRILL, N. K.
*Incandescent Lamps—Note on the Conductivity of Glass, 78. — CHERRILL, N. K.
*India-Rubber Compensator, An, for Telegraph, Telephone, Signal and other Wires, 219. — BOZON, R.
Internal Poles, Dynamos with, 319.
Iron and Nickel, The Thermo-Magnetic Properties of, 260.
*Lag in Transformers, The, 509. — AYRTON, W. E., & PERRY, J.
*Letters for Learners and Unprofessional Readers, 30, 52, 75, 128, 153, 179, 214, 233, 258, 288, 320, 349, 373, 408, 438, 477, 504, 543, 566, 595, 689, 753. — KENNELLY, A. E., & WILKINSON, H. D.
*Lightning, Damaged by, 710.
Lightning Guard, Saunders', 413, 711.
*Lloyds, Barnetts and Bosanquet's Bank, Switch-Board at, 37.
Long-Distance Telephony, The Influence of Self Induction in, 480. — VASCHY, M.
*Mechanical Temperature Compensation, A, for the Bifilar Magnetometer, 545.
*Motor-Generators, A Note on, 107. — SNELL, ALBION T.
*Multiple Synchronous Telegraphy, 714. — DELANY, P.
*Odontoscope, Vesey's Electrical, 438.
Output of Dynamos, The, per Unit Weight of Copper, 634.
Overhead Wires of Copper or Bronze, The Erection of, 262.
Pender, Sir John, K.C.M.G., 687.
Petroleum Engine, Priestman's, 763.
Philippine Islands, Telegraphic Communication with the, 763.
*Photometry: The Pentane Standard Lamp, No. 2, 456.
Potential Recorder, An Automatic, 150.
*Property of the Alkalies of Increasing the E.M.F. of Zinc, On the, 287.
*Pumping Plant, Electrical, at St. John's Colliery, Normanton, 565.
Proportional Reading Galvanometer, A, 628. — D'ARSONVAL, A.
*Proposed New Public Telephone System for Cities and Large Towns, A, 313, 372, 542, 624. — MOSELEY, W.
Radiograph, The, 637. — OLIVER, L.
*Regulator, Automatic, for Constant Current or Constant Potential, 56.
*Renewing Telegraph and Telephone Wires, 439.
*Rise and Progress of Telephony in the United Kingdom, 50, 230, 338, 437, 536, 687.
*Royal Meteorological Society's Exhibition, The, 593, 631. — MARRIOTT, W.
Small Resistances, A Thomson Bridge for the Measurement of, 183.
Sound Receiver, A, for Submarine Telegaph Lines, 569. — ADER, M.
*Specific Electrical Resistance of Hadfield's Non-Magnetic-Manganese Steel Wire, Note on the, 470. — FLEMING, J. A.
*Switch-Boards, Large, for Distribution Work, 619, 654.
*Switches, Incandescent Lamp, 417.
Switches, Independent, Arrangement of, for One Lamp, 263.
*Switches, New Accumulator and Electrolier, 711.
Telegraphing to Moving Trains, 162. — RUDD, C. H.
Tests of the Julien Accumulator, 192. — PRESCOTT, G. B., Jun.
Thermo-Dynamics, Electro-Chemical, 322. — GIBBS, J. WILLARD.
*Thermo-Magnetic Generator and Motor, The Menges, 231.
*Thermo-Magnetic Generators, Early Researches in, 258, 284.
*Thermo-Magnetic Motor, Cooper's, 261.
*Thermo-Magnetic Properties of Iron and Nickel, The, 383, 433. — TOMLINSON, H.
*Trade Discounts, Note on, 13. — MONEY-KENT, J. M. V.
*Transformers, Jablochkoff's, 480.
*Turbo-Electric Generator, Clarke, Chapman and Parsons, 102.
*Type-Writer, An Electric, 155. — HIGGINS, F.
*Unequal Heating of Dynamo-Brushes, The, 103. — MORDEY, W. M.
*Use of Accumulators, The, for Telegraphy by the Exchange Telegraph Company, 215. — HIGGINS, F.
*Voltmeter, "Standard," Capt. Cardew's, 81.

Letters to the Editor.

Alternate-Current Transformers .... MANVILLE, E., 552.
"ELECTRICAL ENGINEER," 671.
"STUDENT, A," 721.
"STUDENT SOC. T.-E. AND E.," 721.
MORDEY, W. M., 761.
Arc Light Carbons .... CATHCART, C. F., 390.
Ball Unipolar Dynamo, The .... ANTHONY, W. A., 272.
Battery v. Alternate Current-Transformers .. CRAWLEY, C. W. S., 484.
CROMPTON, R. E., 521.
Battery Carbons .... "CARBO," 360.
ATKINS, G. J., 389.
LIEPMANN, H., 389.
Bradford Electric Lighting .... M'GOWEN, W. T., 222.
Coefficient of Self-Induction, The .... G. B., 360.
FLEMING, J. A., 389.
Conductivity of Glass, The .... PROCTOR, C. F., 116.
CHERRILL, N. K., 142.
Conversazione, The, of the S. T. E. and E. .... WEBB, F. H., 166.
Cost of Electric Light Fittings .... "MECHANIC," 63.
"Cowles" Process, The .... FAURE, C. A., 87.
Cuttriss Siphon Recorder, The .... CUTTRISS, C., 413.
D'Arsonval's Galvanometer .... SAYERS, W. B., 762.
Deep-Sea Cable Soundings .... BRIGHT, C., Jun., 62.
De Khotinsky Incandescent Lamp, The ...... DE KHOTINSKY, A., 521.
Deposition of Aluminium, The .... NEVILE, R. H. C., 454
Diseases of Dynamos, The .... ESSON, W., B., 114.
STATTER, J. G., 142.
Edinburgh Gas Works, Purchase of the ...... GEIPEL, W., 16.
Efficiency of Incandescent Lamps .... AYRTON, W. E., 481.
Electric Traction .... BERGHOLT, E., 521.
Electric Traction: Closed Conduit Systems .. POLLAK, C., 452, 580.
AYRTON, W. E., 481.
GEIPEL, W., 482.
Electricity and Doctors .... LOBB, H., 301.
Electrolysis of Persalts of Iron .... GORE, G., 168.
Employment of Permanent Magnets for Siphon Recorders .... DICKENSON, W., 272.
Exhibiting Inventions at Exhibitions .... FAHIE, J. K., AND SON, 413.
Fire Office Rules .... RAWLINS, W., 87.
MACDONALD, F. B., 116.
"ELECTRICAL CONTRACTOR," 522.
RAWSON, F. L., 552.
"ANOTHER ELEC. CONTRACTOR," 553.
"INSTALLERS," 580.
PARIS, E. A., 580.
"CONTRACTOR NO. 3," 614.
False Zero Method, The .... RIMINGTON, E. C., 306.
SUMPNER, W. E., 359.
First Use of Accumulators for Electric Traction WARD, R., 613.
Gas Lighter, Electric .... R. H. W., 762.
Glass Condensers .... HIGGINS, F., 672.
"Handbuch der Elektricitat und der Magnetismus" .... ZETSCHE, E., 301.
Independent Switches for One Lamp .... NEVILE, R. H. C., 300.
India-Rubber Compensators for Overhead Wires BOZON, R. G., 273, 327.
CAWS, F., 300, 482.
Inductance and Resistance in Telephone Circuits .... HAWES, F. B., 452.
HEAVISIDE, O., 482.
Inductor Dynamo, The .... KINGDON, J. A., 484.
Inquiry, An .... HARDY, W., jun., 143.
Insulation for Armature Wires .... BENN, E., 763.
Lifeboats, Electrical .... JOHNSON, F., 763.
Lighting of the American Exhibition, The .... HORNSBY, RICHARD, AND SONS, 167.
LAING, WHARTON AND DOWN, 196.
Lightning Protectors .... STALLIBRASS, E., 762.
Measurement of Magnetic Lag, The .... BLAKESLEY, T. H., 482.
Medical Electricity .... MONEY-KENT, J. M. V., 223.
HARNESS, C. B., 274.
Notation, The, of Magnetic Quantities ...... SWINBURNE, J., 412, 483.
HOSPITALIER, E., 451.
Overhead Wires, The Stability of .... CAWS, F., 63, 114, 300, 360, 482, 522, 533.
BOZON, R. G., 273, 327, 452, 522.
PREECE, W. H., 327, 452, 521.
HIGGINS, F., 482.
WALKER, D., 654.
"Papers of Fleeming Jenkin," The .... SMITH, WILLOUGHBY, 761.
Phenomena of Retardation in the Induction Coil, The .... SNELL, A. T., 273.
Post-Office, The, and the Telephone Companies MACIVER, K., 358.
"JUSTICE," 359.
Primary Batteries: a Challenge .... WEBSTER, W., jun., 63, 117.
ROSS, O. C. D., 90.
SHIPPEY, A., 90.
Primary Batteries for House-Lighting .... ROSS, O. C. D., 15, 89, 142, 196.
THOMPSON, N. G., 38, 116, 167.
PENRUDDOCKE, C., 89.
Primary Battery, The Bennett .... BENNETT, A. R., 39.
Primary Battery, The O'Keenan .... O'KEENAN, C. E., 613.
Primary Battery, The Schanschieff .... MOSER, W. E., 89.
Producing Oxygen Gas by Electrolysis .... SMITH, B. W., 581.

Letters to the Editor (*continued*).

Proposed Association of El ctrical E gineers. — W. W. B., 11.; BERNSTEIN, A., 12.
Proposed Lighting of the City, The .... — FAHIE, A., 453.
Proposed Method of Rendering Retardation of Phase Visible .... — WILBERFORCE, L. R., 553.
Pumping by Electricity in Coal Mines .... — BRAIN, F., 63.
Red Varnish for Incandescent Lamps for a Photographic "Dark Room" .... — J. E., 553.
Reinbold's Aluminium Process .... — WATT, A., 484.
Resistance Coil Boxes, Construction of........ — ANTHONY, W. A., 644, 762.; WILKINSON, H. D., 672.
Royal Victoria Hall and the late Mr. Samuel Morley .... — CAVENDISH, LADY L. C. F., 721.
Safety Devices with Transformers .... — THOMSON, E., 520.
Safety Fuses with Springs.......................... — CUNYNGHAME, H., 328.
Self-Induction .... — LODGE, O. J., 721.; SUMPNER, W. E., 761.
Series and Parallel Transformer Connection.. — MORDEY, W. M., 521.
Shallenberger's System of Street Lighting .... — DARLINGTON, F., 453.
Shettle's, Dr., Experiments .... — SHETTLE, R. C., 168.
Skrivanow Cell, The................................ — P. T. H., 273.
Small Dynamos .... — "ONE OF THE UNPROFESSIONAL READERS," 644.
Specific ElectricResistance of Manganese Steel, The.. — BARRETT, W. F., 520.
Springs on Telegraph Wires........................ — CAWS, F., 63, 114, 300, 360, 482, 522, 533.; MELHUISH, T. W. W., 451.; WALKER, D., 554.
Starting the Dynamo on to the Accumulators — PREECE, W. H., 327.
Static v. Dynamic Balance.......................... — "Mk²," 115.
S. T. E and E. and the Paris Exhibition of 1889 — WEBB, F. H., 327.
Street Lighting in English Towns .... — ELMORE, J. O. S., 521.; CHAMBERLAIN AND HOOKHAM, 552.
Submarine Octuplex Telegraphy.................. — TAYLOR, H., 552.
Swan Fire-Damp Indicator, The .... — HIGGINS, F., 246.
Synchronous Multiplex Telegraphy .... — DELANY, P. B., 714.
Teaching of Electricity, The...................... — LARDEN, W., 38.; WILKINSON, H. D., 62.
Telegraph Inventions and their Inventors .... — ERRINGTON, G. W., 273.
Telephone Infringements .... — SWINTON, A. A. C., 613, 672.; SAWREY, J. S., 644.
Telephone Systems .... — HAWES, F. B. O., 720.
Telephonic Communication with Ships......... — UNBEHAUN, C., 484.
Telephony, Long-Distance.......................... — FRY, J. O., 762.
Temperature at which Nickel Loses its Magnetic Properties .... — TOMLINSON, H., 520.
Tensile Strength of Electrolytic Copper ...... — WATT, A., 116.
Thermo-Electricity .... — SNOWDON, R., 327.
Trade Catalogues .... — KING, MENDHAM AND CO., 169.
Trade Discounts...................................... — WALKER, S. F., 63, 117.; FRICKER, G. C., 88.
Training of Electrical Engineers, The .... — CARPENTER, W. LANT, 87.; WALKER, S. F., 88.; "AN ELECTRICAL ENGINEERING STUDENT," 115.
Type-Writing Telegraphs .... — HIGGINS, F., 88.
Wattmeter Measurement .... — WILBERFORCE, L. R., 580.; BLATHY, O. T., 612.; FLEMING, J. A., 670.
West India Cables, The .... — G. N. R., 481.
Working Men's Conference on Technical Education .... — CONS, EMMA, 117, 360

Scientific Societies, Papers, &c., read before.

American Institute of Electrical Engineers.
Alternating Current Electric Motors, 471. — DUNCAN, L.
Discussion on, 474.
Carbon as a Positive Element, 270. — CASE, W. E.
Incandescent Lamps, The Maximum Efficiency of, 754. — HOWELL, J. W.

Belgian Society of Electricians.
Overhead Circuits for Long-Distance Telephony, 447. — BANNEUX, J.

British Association (Manchester Meeting, 1887).
Action of an Electric Current, The, in Hastening the Formation of Lagging Compounds, 84. — GLADSTONE, J. H.
Atmospheric Electricity, Observations on, 182. — WEBER, L.
Determination of the Electromotive Forces of Voltaic Cells, The Application of the Deci-Ampere on the Centi-Ampere Balance to the, 130, 272. — THOMSON, Sir W.
Electric Osmose, and Electro-Capillary Action, 182. — SNOWDON, R.
Electrolytic Decomposition of Certain Alloys, Experiments on the Possible, 57. — ROBERTS-AUSTEN, W.C.
Discussion on, 58.
Mining Lamp and Fire-Damp Indicator, 160. — SWAN, J. W.
Ohm's Law in Electrolytes, On, 385. — FITZGERALD, G. F., and TROUTON, F.
Discussion on, 386.
Report of the British Association Committee on Electrical Standards, 85.
Standards, Electrical Report of the British Association Committee on, 85.
Thunderstorms, The Different Varieties of, and a Scheme for their Systematic Observation, 85. — ABERCROMBY, Hon. R.

Chicago Electric Club.
Comparative Value of Continuous and Alternating Current Systems for the Commercial Distribution of Electricity, 604. — LEONARD, H. W.

City and Guilds Technical College.
Technical Education, 19. — THOMPSON, S. P.

Electrotechnische Verein, Berlin.
Series Glow Lamps, 289. — SIEMENS, W.

Finsbury Technical College Old Students' Association.
Diseases of Dynamos, The, 82. — THOMPSON, S. P.
Discussion on, 84. [*See also* p. 282.]

Institute of Civil Engineers.
Bessbrook and Newry Tramway, The, 104. — HOPKINSON, E.
Electric Traction—Direct Current Working *versus* Accumulators, 410. — LINEFF, A.
Presidential Address, 3. — BRUCE, G. B.
Safety Lamps, Electric, 40. — ABEL, Sir F.

Institution of Mechanical Engineers.
Position and Prospects of Electricity applied to Engineering, 354, 379. — GIEPEL, W.
Discussion on, 424.

Middlesex Natural History and Science Society.
Position and Prospects of Electric Lighting in the Metropolis, The, 248. — CARPENTER, W. LANT.

National Electric Light Association of America.
Arc Light Carbons, 479. — PARKER, G. W.
Central Station Lighting—Independent Engines in Independent Stations, 513. — CHURCH, W. L.
Distribution of Electricity, The, by Alternate Currents, 547. — SMITH, T. C.

Physical Medical Society of Erlangen
Effect of Light on the Electric Discharge, On the, 324. — WIEDEMANN, E., and EBERT, H.

Physical Society.
Effect of Magnetisation, The, on the Thermo-Electrical Properties of Bismuth, 330. — TOMLINSON, H.
Efficiency of Incandescent Lamps with Direct and Alternating Currents, On the, 454. — AYRTON, W. E., & PERRY, J.
Experiments on Electrolysis, 486. — GEE, W. W. HALDANE.
Influence Machines and Dynamos, The Analogies of, 91. — THOMPSON, S. P.
Influence of Magnetism and Temperature, The, on the Electrical Resistance of Bismuth and its Alloys with Lead and Tin, 330. — AUBEL, E. VON.
Magnetic Circuit in Dynamo Machines, The, 555. — AYRTON, W. E., & PERRY, J.
Measurement, The, of the Power supplied to the Primary Coil of a Transformer, 554. — RIMINGTON, E. C.
Discussion on, 554.

Physical Society—(*continued*).
New Pattern of Reflecting Galvanometer, with Lamp and Scale, 517. — ADDENBROOKE, G. L.
Optical Demonstration of Electrical Stress, The, 330. — RÜCKER, A. W., and BOYS, C. V.
Price of the Factor of Safety in Lightning Rods, 330. — THOMPSON, S. P.
Rotation of a Copper Sphere and of Copper Wire Helices when freely suspended in a Magnetic Field, 143. — SHETTLE, R. E.
Temperature, The, at which Nickel begins suddenly to Lose its Magnetic Properties, 486. — TOMLINSON, H.
Discussion on, 486.
Thermo-Electrical Properties of Iron, On the, 92. — TOMLINSON, H.
Use of the Term "Resistance," The, in the Description of Physical Phenomena, 393. — BOSANQUET, R. H. M.
Discussion on, 393.
Variation of the Coefficients of Self-Induction, 713. — SUMPNER, W.E.
Discussion on, 714.
Water Dropping Influence Machine, A, 339. — THOMPSON, S. P.

Physical Society of Glasgow University.
Electrolysis of Copper Sulphate, The, in Standardising Electrical Instruments, 571. — MEIKLE, A. W.
Improved Apparatus for the Determination of the Intensity of the Horizontal Component of the Earth's Magnetic Field, 393. — GRAY, T.

Royal Colonial Institute.
Telegraph System of the British Empire, The, 509. — HEATON, J. HENNIKER, M.P
Discussion on, 510.

Royal Institution.
Safety Lamps in Collieries, 377. — PREECE, W. H.

Royal Meteorological Society.
Non-Existence of Thunderbolts, The, 545. — SYMONS, G. J.

Royal Society.
Changes produced by Magnetisation in the Dimensions of Rods and Rings of Iron and of some Other Metals, 538. — BIDWELL, S.
Heating Effects of Electric Currents, On the, 386, 411, 718. — PREECE, W. H.
Specific Inductive Capacity, 187. — HOPKINSON, J.

Society of Arts.
Application of Electricity to Lighting and Working, The (Juvenile Lectures), 690, 736. — PREECE, W. H.
Mercury Air Pump, The History and Development of, 63. — THOMPSON, S. P.

Society of Engineers.
Primary Batteries for Illuminating Purposes, 17, 37, 64. — NURSEY, PERRY F.
Discussion on, 66.

Society of Telegraph Engineers and Electricians.
Alternate-Current Transformers, with Special Reference to the Best Proportion between Iron and Copper, 338, 381. — KAPP, G.
Discussion on, 419, 441, 487.
Central Station Lighting—Transformers v. Accumulators, 634, 655. — CROMPTON, R. E.
Discussion on 656, 694, 749.
Deep Sea Soundings in Connection with Submarine Telegraphy, 39. — STALLIBRASS, E.
Discussion on, 40.
Electrical Stress, 599. — RÜCKER, A. W., & BOYS, C. V.
Discussion on, 602.
Fire Telegraphy, The Present State of, 522. — TREUENFELD, F. VON.
Discussion on, 523.
Formulæ for Converters, 408. — FORBES, G.
Measurement of Electromotive Force and Electrical Power, Some Instruments for the, 109, 136. — FLEMING, J. A., and GIMINGHAM, J. H.
Discussion on, 91, 111, 143.
Portable Voltmeters for Measuring Alternate Potential Differences, 206, 242, 268, 296. — AYRTON, W. E., & PERRY, J.
Discussion on, 91, 111, 143.
Presidential Address to the Society of Telegraph-Engineers and Electricians, 246, 274. — GRAVES, EDWARD.
Safety Fuses for Electric Light Circuits, 298. — COCKBURN, A. C.
Discussion on, 328
Use of Electricity for Theatre Lighting, 712. — TIDD, G.

South Wales Society of Engineers.
Electric Pumping in Collieries, 139. — BRAIN, F.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 495.—Vol. XX. FRIDAY, NOVEMBER 11, 1887. Price 4d.

NOTES.

With the present week's issue of *The Electrician*—the first of a new volume—some alterations will be noticed in its make-up and general appearance, which we feel sure will be welcomed by our readers. The journal is enlarged by four pages, the paper on which it is printed is better, and its letterpress, besides being improved, has been readjusted with a view to giving greater freedom in the distribution and treatment of its miscellaneous contents. Some further improvements are contemplated, which will be noted in due course.

Naturally the gas journals are not friendly to our proposed Electrical Engineering Association, and they gladly avail themselves of the objections urged against it by *Engineering* in the article on which we commented last week. We are glad to notice, however, that a fairer tone pervaded a subsequent leader on the same subject in the last-named journal; and we entertain a hope that when it has taken the trouble to ascertain more exactly what the objects of the scheme really are our contemporary may adopt a more friendly attitude towards it.

In reference to the last chapter of the papers on the "Rise and Progress of Telephony in the United Kingdom," Prof. Silvanus Thompson writes us to point out that the quotation (on page 533) from his evidence at the trial of the United Telephone Company *versus* Harrison, Cox-Walker is not an accurate version of what he actually said. The sentences in question were quoted by the writer of the article from an abridged report in a contemporary journal. From the transcript of the shorthand writer's notes it appears that what actually took place was the following:—

Mr. Justice Fry: What you say is this: When you used it in a manner it was not intended you might occasionally get out articulate sounds?

Prof. Thompson: I think he *did* intend it to speak.

We gladly take the opportunity to amend the quotation, but may add that the writer of the article was not disputing the fact or the intention of Reis to make a speaking telephone. The question was whether the *modus operandi* was by actual make-and-break or by microphonic action; and the argument tended to show that while Reis aimed at a make-and-break his success was due to a microphonic effect. The quotation from the evidence of Prof. Silvanus Thompson, even in its amended form, does not upset this argument.

The chairman of the Imperial Continental Gas Association, being questioned at its half-yearly meeting as to the reasons the company had for undertaking the lighting by electricity of the Burg Theatre at Vienna, replied that there were special circumstances which rendered that course desirable. He did not state precisely what those circumstances were; but he furnished one reason, which he seems to have thought good enough to satisfy the dissentient English shareholders. This was that "if we can show our [electric lighting] competitors what the cost of an electric lighting station is, and what return it is likely to give, they will not be so ready to enter the field as they otherwise would be." A shrewd suspicion that this might be the ingenious motive of certain gas companies nearer home in seeking powers to supply the electric light may have induced the Board of Trade some time ago to refuse their applications. We entertain no doubt that the gas companies will one day be glad to take up their competitor's business, not for the purposes of discrediting it but of working it for profit. Meanwhile, nobody will attach much value to their estimate of what an electric station ought to cost or what the profits are likely to be.

Since writing the above note we came across the following telegram in the colums of a daily contemporary, which we add without further comment:—"Disputes have again broken out between the Imperial Continental Gas Company, which supplies the electric lighting for the Vienna Opera House, and the local authorities, in consequence of which the light supply for the opera has been discontinued and the performances consequently suspended. For some time past the company has been experiencing considerable difficulty in keeping up a regular supply, owing to the defective nature of the boilers, which, yielding to the pressure of the local authorities, the company consented to have made in Austria instead of in England, as they wished. As it is deemed necessary by the authorities to have all the boilers thoroughly overhauled, the result is that the Opera House will be closed for the next fortnight."

The case of Ferranti *v.* Gaulard-Gibbs will not improbably come before Mr. Justice Kekewich within the next few days. It is, in fact, set down for Monday, but whether or not it will be heard on that day is somewhat uncertain. As many of our readers will be aware, the case is one of very great importance for the future of long-distance lighting, although, unfortunately, the issue will scarcely be conclusive as to the patent rights in transformers whichever way it may result. Mr. Ferranti is peti-

Digitized by Google

tioning the Court to annul the most important of the Gaulard-Gibbs patents on either or both the grounds of alleged flaws in the specification and alleged impropriety of the subject matter for the grant of letters patent. Proceedings of later date have also been set on foot by Messrs. Gaulard and Gibbs, in which damages are claimed against Mr. Ferranti for infringement of their patent claims.

A rumour from the City reaches us as we go to press that the dispute above alluded to has been settled out of court.

Speaking at Bath last Friday the Chancellor of the Exchequer expressed his determination not to part with the two and a-half millions of revenue which the Post Office annually delivers over to the Treasury by way of profit on the letter-carrying business. We commend this resolution, and hope Mr. GOSCHEN, to quote his own words, will defend the surplus with his life. He regards the inland postage as a very light and unobjectionable instrument of taxation, the net proceeds of which, if applied to the reduction of rates on foreign postage instead of to the relief of the financial burdens of the country, would entail upon the whole of it additional imposts for the benefit of a particular section. Mr. Henniker Heaton will doubtless take note of this. These views, moreover, are similarly applicable to other great corporate industries, notably the great telegram-carrying businesses; and it may be hoped that when next the tariffs of the cable companies are the subject of international discussion, the Chancellor of the Exchequer will defend them on the same business-like principles against those who would appropriate the legitimate rewards of a class which is chiefly English in order to benefit communities which are largely foreign.

According to the *Central News*, whose report on the subject will be found in another column, the effect of the expiry of the Submarine Telegraph Company's cable monopoly to France will be that the British Postmaster-General will have the whole control of the Channel cables in his own hands. Our impression is that this will not be the case. The Submarine Company having actually obtained an extension of its concession for another fifteen years, neither the British Post Office nor anybody else other than the Submarine Telegraph Company will be able to land cables on the French coast without the permission of that company. If this view be correct the matter is one for mutual arrangement between the parties.

The paper on Primary Batteries, for illuminating purposes, read by Mr. Perry F. Nursey before the Society of Engineers on Monday evening, presented a useful compendium of the various attempts which have of late years been made to solve the problem in question. Mr. Nursey was doubtless well advised when he declined to attempt any criticism of the relative merits—or demerits—of these batteries. The fraternity was there in full force, and eager for the blood of any one who dared to find an imperfection in their respective inventions. As it was, they had no grounds of complaint, for, as Mr. Nursey was careful to explain, the descriptions and figures were those furnished by the inventors themselves. The description of one cell which is even capable of running lamps of different candle-power on the same circuit was evidently quoted from a recent article in one of the daily papers. The old *ignis fatuus* of residual products was again trotted out in fine form; and it was really very unkind of Mr. Preece, in the subsequent discussion, to mention the fact that even at the General Post Office, where several hundred thousand cells are in use, the residual products can never so much as be made to pay for the cost of collection. There is one cell, however, which really does appear to us to have a chance in this direction, if we rightly understand the claim made by its representative. This remarkable cell was stated to use 500 per cent. less nitrate of soda than a certain other cell which was mentioned. If this means anything, it indicates that for every pound of nitrate of soda used in the latter, the former produces 4lb. of the same salt. Several of the batteries mentioned by Mr. Nursey were, of course, of considerable value in their proper spheres. They may generally be recognised by the fact that their inventor's claims for them are of a modest character. A man who is a sufficiently good electrician to produce a really practical and efficient primary battery is far too good a one not to know that as regards electric lighting the sphere of the primary battery is very limited in point of scale, although it may be wide in extent.

Apropos of primary-battery-ism, a rather interesting fact was mentioned to us by one of the audience who had listened to Mr. Nursey's paper. He was thinking, he said, of putting in a P.B. for lighting a small house, and with that end in view went to sundry of the companies to inquire as to the cost and other details of their respective "systems." He said that in several cases their respresentatives seemed quite unable to grasp the idea that he actually wanted to *buy* a battery—the possibility of such a proceeding never seemed to have entered their heads; so they tried to persuade him that he really must be mistaken, and that what he actually wanted was to take shares in their company, which they could assure him, &c., &c.

A little consideration is, we fear, sufficient to show that the "residual products" idea in primary battery lighting is based upon what is, perhaps, little better than an economic fallacy. For, supposing that a battery had been devised in which the residual products were of sufficiently high value to pay the cost of collection when working upon a sufficiently large scale, then it is obvious that the whole of this cost could be saved by carrying out the same chemical operation at one spot. But it is certain that the chemical process would then be carried out under conditions very far more favourable to economy than in the makeshift style of a battery cell. We should thus have to set off the value of the light obtained against the diminished cost of the residual products when made on a manufacturing scale. It is obvious from these considerations that the chances in favour of the permanent value of the residual products must be in general very small indeed. The most favourable chance on record was probably that of the chromate of calcium cell devised many years ago by Mr. D. FitzGerald. We believe we are correct in saying that this

Digitized by Google

battery practically created the market for its own bye-product, with the result that, as soon as the demand was felt, other processes were introduced, which soon brought the value down to a point where any further competition on the part of the battery was hopeless.

Projectors.—It is stated that the Peninsular and Oriental Steam Navigation Company have given an order for twelve Mangin projectors to MM. Sautter, Lemonnier and Co.

Submarine Cables.—The *Leisure Hour* for November contains an article by Mr. J. N. Porter, giving details of the principal submarine cables and the land-lines in connection all over the world.

Telegraph Stores Required.—Tenders for the supply of telegraph stores have been invited by the following companies:—The Midland Railway Company, the South Indian Railway Company, and the Cheshire Lines Committee.

The Union Bank—Messrs. Elwell-Parker (Limited) are supplying to Messrs. B. Verity and Sons two 12-unit dynamos, and 106 large cells for the Union Bank of London installation, which we hear is approaching completion.

Club Lighting.—The new Isthmian Club, in Piccadilly, which was opened on the 1st inst., is lit by Ferranti transformers, supplied with current from the Grosvenor Gallery. The wiring and fittings were supplied by the Woodhouse and Rawson Company.

Electric Tramways in Brazil.—The *Rio News* says that a proposal for a thirty-years' privilege for an electric tramway in Petropolis, put forward by Mr. Albert Hargreaves, has been referred to the provincial assembly by the president of the province of Rio.

The Electric Light in Brazil.—Mail advices, dated Rio de Janeiro, October 15, state that a new electric company, called the Companhia Força e Luz, was organised on the 10th of October, its principal object being the supply of electric light for private consumption.

Electric Traction at Cologne.—MM. Huber and Herebrand, of Ehrenfeld, have recently placed electric cars upon the tram lines at Cologne. The batteries were furnished by the Electric Power Storage Company. The preliminary trials are said to have been successful, but we have no further details at present.

Country House Lighting.—We understand that the installation erected some years back at Lord Armstrong's mansion, Cragside, is being considerably extended and improved. Messrs. Drake and Gorham are carrying out the work, in connection with which fifty-three of their largest type cells are to be used.

The "Phil. Mag." for November.—This month's *Phil. Mag.* contains an interesting paper by Prof. E. Edlund on the (so-called) Unipolar Induction. The only other paper of an electrical character is a reprint of Mr. Fitzpatrick's British Association paper, "On the Action of the Solvent in Electrolytic Conduction."

Bank of England.—The extension of the lighting is progressing rapidly. We understand that the new plant consists of a 20 horse-power Marshall horizontal engine and boiler and two Elwell-Parker 18-unit dynamos. A battery of Drake and Gorham's accumulators will also be employed in connection with each circuit.

St. Leonards.—At a banquet given in this town by Mr. Wilson Noble, M.P., the borough member, to the corporation and borough officials on the 1st inst., the entertainment, which took place at the Grand Hotel, was lighted exclusively by electricity. The local newspapers speak of the installation in terms of the highest praise.

A Disputed Claim.—A case of some interest is to come before the Courts next week, in which Messrs. Sharp and Kent sue M. F. D'Humy for the recovery of a sum amounting to over £100 for carbon plates supplied for use in his water primary battery. M. D'Humy sets up a counter-claim for damages to the extent of £1,000, on the ground that the carbons were bad.

The Clamond Incandescent Gas Light.—We are informed that the installation of "Clamond" incandescent gas lights, employed at the Guildhall on Wednesday last, is the first of the kind in this country. The work was carried out by the Æolus Waterspray Electrical Engineering Company. Each 40 candle-power burner on this system consumes only 6ft. of gas per hour.

Professor Stokes.—The University of Cambridge has chosen the President of the Royal Society as candidate for the Parliamentary seat vacant through the death of Mr. Beresford-Hope. If Prof. Stokes is elected it will be the first occasion on which either of the two great seats of learning has chosen a scientific representative since the time of Sir Isaac Newton, who sat for the Cambridge University in 1688.

Presidential Address at the Institution of Civil Engineers. The opening meeting of the session of the Institute of Civil Engineers was held on Tuesday, the 8th inst., when Mr. G. B. Bruce, president, delivered his inaugural address. Mr. Bruce made a general survey of the progress of engineering during the last fifty years, and concluded by referring briefly to the enormous changes which have followed from the industrial application of electricity.

The Direct Acting Edgerton Electric Pump.—The Edgerton Electric Motor Company, of Philadelphia, is making a speciality of a motor combined with a direct acting high-pressure pump. The pump is of special design, and is double-acting coupled direct to the motor, and works under a pressure of 42lb. to the square inch. A half-horse power plant has a capacity of 300 gallons per hour, and occupies a floor space of 3ft. by 10ft. A considerable demand is found to exist where current is available.

Tenders for Theatre Lighting.—A correspondent writes from Madeira:—"I shall feel much obliged if you will kindly draw the attention of your numerous readers to the fact that the Municipality of Funchal have published an advertisement in the *Diario de Noticias*, inviting tenders for lighting the new theatre 'D. Maria Pia,' and the City of Funchal with electric light. Applications for plans and all particulars should be addressed to the President of the Municipality, the Visconde do Ribeiro Real, Funchal, Madeira."

A Pretty Lecture Experiment.—A ring of copper is placed round the neck of an empty corked bottle, which is further weighted till it will just sink, neck downwards, when placed in a larger glass vessel of water. Round the lower part of the latter are wound a few turns of insulated wire. When an alternating current is passed through the wire the flask will be seen to rise, owing to the repulsion between the currents in the wire and those induced by them in the ring. The experiment is due to Prof. Elihu Thompson.

Adelaide Jubilee Exhibition.—We have pleasure in announcing that Messrs. Robey and Co., Globe Works, Lincoln, have been awarded six first prizes at the Adelaide Exhibition for their horizontal automatic engines, compound portable

Digitized by Google

engine, portable winding engine, wrought angle iron-framed thrashing machine, patent Robey winding engine with wrought iron tank foundations and centrifugal pumps.—We are also glad to learn that Messrs. Ransomes, Sims and Jefferies (Limited), of Ipswich, have been awarded the first order of merit for their exhibits, which include portable steam engine, vertical engine and boiler, single and double furrow ploughs, patent chilled ploughshares and horse rakes.

Electric Light Statistics for Germany.—According to Dr. Schilling, the number of electric light installations in the thirteen principal towns of Germany has increased during the last two years from 131 to 604; the number of arc lamps has increased from 591 to 3,280, and the number of incandescents from 10,403 to 50,469. The number of gas lamps in these thirteen towns is 1,221,882, and therefore, lamp for lamp, electricity furnishes about 4 per cent. of the total illumination. In Munich this proportion is as high as 8 per cent. According to another authority there are in Hamburg at the present time 78 installations of electric light; 325 arc lamps and 5,300 incandescents. About 1,000 horse-power is employed for these installations, of which one-fifth is furnished by gas engines.

The Society of Arts.—The first meeting of the one hundred and thirty-fourth session of the Society of Arts will be held on Wednesday, the 16th November, when the opening address will be delivered by Sir Douglas Galton, K.C.B., D.C.L., LL.D., F.R.S., Chairman of the Council. The papers so far arranged for which relate to subjects of interest to our readers are as follows:—November 23rd, Prof. Silvanus P. Thompson, on "The Mercurial Air-Pump." December 14th, Sir Philip Magnus, on "Commercial Education." A course of Cantor lectures on "Alloys," by Prof. W. Chandler Roberts-Austen, F.R.S.; and two juvenile lectures on "The Application of Electricity to Lighting and Working," by Mr. W. H. Preece, F.R.S, which will be given during the Christmas holidays.

Birmingham.—The "Wild West" Show has "moved," and is now performing at the Aston Grounds, Birmingham. At present the performance is only during the daytime, but by next Monday it is expected that the electric light will be in operation, and night performances will then commence. The electric light arrangements are practically the same as at the American Exhibition at West Brompton, and consist of ten large projectors, each taking a current of 50 amperes supplied from two Victoria dynamos. Either of these machines is large enough to light the total number of lamps by itself. The contract for this work has been entrusted to the United Electrical Engineering Company (Limited) (Messrs. Manville and Madgen). This firm has undertaken to get the light running by Monday next, although the order was only received on Saturday last.

The Lighting of the Monnaie Theatre at Brussels.—The installation at the Monnaie Theatre at Brussels possesses a feature of considerable interest in the fact that the current is supplied by accumulators in the basement of the building, which are charged by machines situated at a distance of 4 kilometres. The number of lamps employed exceeds 600, varying from 8 to 30 candle-power, with a terminal potential of 110 volts. Very elaborate switching arrangements are made for the lighting of the stage. The generating station is situated next to the gas works at Laeken, where an Armington-Sims engine of 80 horse-power drives a 30-unit Gérard dynamo giving 15 amperes at 2,000 volts. This machine is separately excited by two smaller Gérard machines of 110 volts. The commercial efficiency of the system is given as 88 per cent. The dynamos are in duplicate, but there seems to be only one engine. The effect in the theatre has been to reduce the temperature from 45°C. to 18°C., and great satisfaction is expressed with the result.

Trial of Electric Tramway Car at Paisley.—A local journal says:—Mr. James Gibson, electric engineer, Cartha Works, Paisley, has constructed an electric tramway car, and an experimental run was made on Thursday, on the line of the Paisley Tramway Company from Gauge-street to Williamsburgh. The experimental run was considered highly satisfactory. Eighty storage cells supply current to the motor, which rests on a bogey, placed to the front of, but under, the car, and the bogey also includes the front wheels of the car. This arrangement has been adopted for simplicity in the working of the car, as the one bogey, when the accumulators are exhausted, can be easily taken from the car and a new one put in. The motor makes 1,200 revolutions per minute, and a speed can be obtained from four to fifteen miles per hour. When the car is going at the rate of four miles per hour, it can be brought to a stop within the space of two feet from the applying of the brake. In connection with the machinery there are two systems of gear—the one a combination of friction and teeth gear, and the other teeth gear alone.

The Heriott-Watt College, Edinburgh.—Complete arrangements are being made at the Heriott-Watt College for courses in electricity and electrical technology. Laboratories, with every appliance for systematic practical instruction in physics, and a dynamo and test room with power and all testing instruments are being fitted up in the new buildings. Pending the completion of these the Governors have procured the use of the lecture rooms in Minto House. The former courses in the theory of electricity have been extended, and on Friday last a commencement was made with the lectures on applied electricity. The electric lighting and engineering, and telegraphy and telephony classes are presently to be merged in one. Principal Ogilvie gives six preliminary lectures, after which it is expected that students will be prepared to enter the special branch they propose to take up. Mr. W. Geipel, who is district manager of the Brush Electric Light Corporation, will then continue the lectures on electric lighting; those on telegraphy and telephony being taken up by Mr. Alfred Campbell, of the Electrical Staff, North British Railway.

Hastings.—The Town Council last Friday was the scene of some lively episodes in relation to matters connected with electrical industry. The Roads Committee reported against the application of the South of England Telephone Company for permission to erect two wooden telegraph poles on the east side of Old London-road; also against a request of the Hastings and St. Leonards Electric Light Company that they be allowed to erect overhead wires from the company's works in Earl-street to the Palace and Grand Hotels. On both these reports, which were ultimately adopted by small majorities, a warm discussion took place, in the course of which a ratepayer present had to be turned out for expressing his feelings too strongly. The proceedings were diversified by legal doubts arising in the mind of the Town Clerk as to whether this or that member of the Council was competent to speak or vote by reason of his pecuniary interests in one or other of the local companies affected. As nearly all the Council appear to be holders of either gas, electric light, or telephone shares, the proceedings were proportionately shortened; and subsequently a motion to inquire into the relative purity of gas and electric light was summarily stopped because of the mover being a shareholder in the Electric Light Company.

A Water-Level Indicator.—Electric water level indicators are as common as blackberries, and we are not prepared hastily to assert that the apparatus about to be described contains anything absolutely novel. However this may be, it is certainly an ingenious device, and additionally interesting as being the work of a schoolboy (W. A. Tucker) sixteen years of age. A hollow ball float is mounted on the end of a long lever, which is pivoted towards the other end on the edge of the tank, so that the short end of the lever projects beyond. When the tank is full the lever assumes a horizontal position; when empty the short end projects upwards at an acute angle. It only remains to allow the short end to close a set of rubbing contacts in its different positions, and thus to transmit signals to an electric bell or annunciator as may be desired. By the use of a closed circuit and a little additional complication it would, no doubt, be possible, with only two wires, to indicate differences of level within a tolerably fine graduation. Mr. W. A. Tucker is the son of a Col. Tucker, of Boston, United States.

The Use of Electricity for Treating Gold and Silver Ores.—On September 16th we mentioned that a new process of dealing with silver ore, which involved the use of dynamos, was being taken up in Nevada. We now learn that the method, which is due to Mr. Molloy, of the Hydrogen-Amalgam Company, consists in placing ground ore in a flat pan containing mercury and water; in the centre of the pan is a porous pot which contains a lead plate in a solution of sulphate of soda. An annular disc surrounds the porous pot and floats upon the surface of the mercury. The material of which this disc is made is not stated; it is, however, caused to rotate very rapidly so as to effect an intimate mixture of the ore with the mercury. The whole of the mixed materials are thus "urged out at the rim of the disc by centrifugal force." Meanwhile, it should be stated that the lead plate in the porous pot is connected with the positive terminal of the dynamo, and the mercury in the pan with the negative terminal. Hydrogen is thus evolved upon the surface of the mercury from the water in the pan, and thus overcomes the tendency to oxidise, or "sicken," as the workmen call it. It is claimed that as much as 40 per cent. more gold can be extracted in this way; and as in addition to this the waste of mercury by oxidation is almost entirely obviated it is clear that the process, if this be true, is one of great practical value. We are, however, under the impression that something very similar has been tried before, though, for some reason or other, no ultimate success was attained.

A Method of Making a Selenium Cell of Constant Resistance.—M. Mercadier promises shortly to explain a new system of multiple telegraphy based upon the employment of the selenium cell, of which, as is well known, he has made a special study. In the year 1881 M. Mercadier first described a method of making a low-resistance selenium cell for use as a radiophone receiver. This method consisted in taking two thin strips of brass, separated by a sheet of paper, and drawing a stick of melting selenium along the edges. It was, however, found that the selenium deposited in this way was very apt to scale or chip off, and, moreover, it was almost impossible to make two cells of this pattern which should have the same resistance. He therefore constructed a somewhat different form of cell, which, although now described (in the *Comptes Rendus*) for the first time, has yet remained unaltered in resistance for over six years, and it has also been found an easy matter to make other cells of the same resistance. A pair of platinum wires are accurately laid down in the form of a double spiral upon a sheet of emery paper. The ends of the wires are attached to two separately insulated blocks of brass upon which the emery paper rests. The whole is then heated to the melting point of selenium, and a stick of that material is drawn around the double spiral. This would scarcely seem to be a very easy mode of constructing a set of identical cells, but in M. Mercadier's hands the results obtained are excellent. Several cells made at different periods since 1881 have each a resistance of about 300,000 ohms, and have not varied since their first measurement.

Notes on the Electric Lighting of the Recent American Exhibition.—The electric lighting of the American Exhibition held during the present year at Earl's Court, with the exception of the search lights in the arena of the Wild West, which were erected by the Anglo-American Brush Corporation, was entirely carried out by Messrs. Laing, Wharton and Down. The Exhibition buildings and grounds were lighted on the Thomson-Houston arc system from seven 50-light dynamos, each giving 2,000 volts and 10 amperes, and two 35-light machines, giving 1,500 volts and the same current strength. The power was obtained from three engines, with an aggregate of 90 indicated horse-power, by Messrs. Hornsby, of Grantham. The installation was carried out under considerable difficulties, as, owing to the delay in getting the shed ready for the reception of the dynamos, it was impossible for the engineers to make a trial run until the very evening of the day on which the Exhibition was opened, when the buildings were cleared for about twenty minutes for the purpose. Everything was found to be in perfect order, and from that time until the closing of the Exhibition the lighting was carried out in the most satisfactory manner. One breakdown only occurred during the whole time of exhibition, and was caused by a tube being blown out of one of the boilers, which necessitated the stoppage of the machines supplying one of the circuits in the building. Even this caused no sensible inconvenience, as the precaution of supplying alternate lamps only from the same circuit had been adopted by the engineers; moreover this cessation was only of about four minutes' duration, as spare machines were immediately switched into the circuit to replace those which had been stopped by the breakdown of the boiler. The Thomson-Houston system of regulation, which is well known to the readers of *The Electrician*, was very severely tested during the first few weeks of the Exhibition. The fitting of the engines, in the first place, was by no means satisfactory, and on some of our first visits to the engine room we have seen as many as three pumps at work throwing water on the bearings to keep down their heating. The action of the Hornsby governors, at any rate as they were run here, did not appear to be sufficient to maintain the steady speed desirable for electric lighting purposes, and this was specially evident when the Thomson-Houston lamps on the mast in the arena of the Wild West were switched on or off, when even the very efficient system of regulation in use was insufficient to prevent flashing. On more than one occasion the engine room was filled with grit from the plugs having been allowed to blow out, and the general state of the engine room, as regards cleanliness, was not such as to excite our admiration, nor probably that of the engineer in charge of the dynamos. The Welcome Club was lighted by incandescent lamps from a Jones dynamo, driven by a 12 horse-power vertical engine. The electroliers were formed of brass and beaten copper in the form of foliage, with lamps shaped like fruit, and excited general attention from their beauty of design.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

The electro-deposition of iron, although it has met with some few applications—but more especially in the so-called "steel facing" of engraved copper plates and printers' type—has not yet received so much attention in this country as it deserves. Indeed, iron-plating—which is a better term than *ironing*, which would smack rather of the laundry—and iron electrotyping may be said to be as yet but in their infancy, so far as development is concerned. There can be no doubt that if iron electrotypes could be as freely obtained as we produce those of copper, a very important field of enterprise would be opened up for those who follow the art of electro-deposition. Before this desirable object can be attained the study of various solutions of iron salts, with and without the addition of other substances, must receive further consideration. With a view to aid those who are interested in the electro-deposition of iron generally, I purpose giving the results of a series of experiments which I have made from time to time in the deposition of iron, from which it will be seen that while there are many iron salts from which the metal may be deposited readily and of good quality, other salts are totally unfit and valueless for the purpose. When desirous of taking up any new branch of electro-deposition, it is advantageous to the student, not only to know the nature and behaviour of those materials which are most suitable for his purpose in a practical sense, but he should also have some knowledge of the shortcomings of other salts of the same metal in case at any time he might be tempted to experiment in the same direction himself.

In depositing iron from its various solutions many difficulties have presented themselves which ingenuity has to some extent overcome. The rapid oxidation of the iron salt of the surface of the electrolyte, and the blackening of the deposit at the corners and edges of the plate have, amongst other sources of annoyance, been the most troublesome causes of failure. Again, with some solutions it has been found that the anode did not dissolve with sufficient readiness to keep the bath up to its normal strength. These faults have, however, been to some extent overcome, and so far as light deposits are concerned—such as in the facing of engraved copper plates—the deposition of iron presents but little difficulty. The production of iron electrotypes, however, has yet to receive further development before the process becomes a practical art of general application.

In describing the various solutions of iron which I have electrolysed, with a view to determine what character of deposit they were capable of yielding, it may be well that I should also refer, in passing, to those solutions which have hitherto been employed or recommended for the deposition of this metal. In making up baths from any of the well-known solutions, I would recommend the operator—regardless of prescribed formulæ—always to make his solution a trifle too weak rather than adopt the other extreme, since weaker solutions will often give far better results than stronger ones, and the gradual strengthening of the bath can readily be resorted to if occasion requires it. Too strong a solution of any iron salt is pretty sure to give an indifferent deposit and cause disappointment, whereas with a weaker solution—if it be a good one in other respects—the deposition is merely slow, a fault easily remedied by the *gradual* addition of more iron salt. The alterations of the strength of the bath should never be made, however, until the operator has satisfied himself that the current is adequate. When practical, the solution (proto-sulphate, for example) should be put into such a condition that it will work well with a surface of anode about equal to that of the cathode, when working at the ordinary temperature. With some solutions, however, this would not be practical, as in cases where other salts besides those of iron are used for preparing the bath, which have little or no solvent action upon the iron anode.

Proto-Sulphate of Iron.—Various proportions of this salt to the gallon of water have been employed in making up baths for depositing iron, but I found the following give exceedingly good results with a somewhat weak current: About half an ounce of good sulphate of iron was dissolved in a pint of cold water. One small Daniell cell was first tried, with electrodes of about equal surface, but the deposit was of rather dark colour. A few drops of sulphuric acid were then dropped into the bath, and an extra cell connected, when a considerable improvement in the colour was manifest; a third cell was now added—the whole being in series—when the deposit became exceedingly white and bright, which character it maintained. At the end of about two hours the plate (sheet copper) was withdrawn, when its brilliant appearance resembled that of copper which has been dipped in mercury. There was considerable evolution of hydrogen. On examining the anode (a plate of wrought iron), it was found to have been very equally and very freely acted upon, and presented a very clean surface.

Proto-Chloride of Iron.—A moderately strong solution of this salt did not yield a good deposit; neither was the colour of the film improved by diluting the solution. In all conditions of the liquid the deposited metal had a tendency to blacken after a short immersion of the negative plate. The best results were obtained with two Daniell cells.

Ammonio-Sulphate of Iron.—A solution of this salt, used with a rather weak current, is undoubtedly one of the best for the deposition of iron. The solution is greatly improved, however, by the addition of a moderate quantity of acetic acid. I found the following proportions yield a very white deposit of iron with two small Daniell cells:—Ammonio-sulphate of iron 1¼oz., water one pint. The deposit, though not so bright as that from the proto-sulphate before referred to, was very white and uniform in character; there was no blackening of the film at the corners of the plate, and deposition took place very freely.

Tartrate of Iron.—A solution of this salt was prepared by dissolving recently precipitated hydrated sesquioxide of iron in a strong and hot solution of crystallised tartaric acid. With two Daniell cells little or no deposit took place. With five cells the film was white at the lower part of the plate, but the remaining surface was of a dark colour. The solution is a bad conductor, and not suitable for any practical purpose.

Phosphate of Iron.—Recently precipitated carbonate of iron was dissolved in a strong and hot solution of phosphoric acid. Five cells were used, when a white deposit of iron was obtained upon a copper plate almost immediately. The coating soon became dull, however; and after about half an hour or so the liquid became decomposed, a white precipitate being formed, which settled upon both electrodes and floated about in the liquid. The white salt thus formed was doubtless the protophosphate of iron.

Salicylate of Iron.—A solution of this salt was prepared by dissolving recently precipitated carbonate of iron in a hot solution of salicylic acid, when a deep red liquid resulted, which yielded a tolerably prompt deposit of iron of a darkish colour, but fairly adherent, upon a copper surface. Five cells were necessary to obtain a successful deposit.

Potassio-Tartrate of Iron.—A solution of this salt yielded a tardy but bright deposit of iron, with five Daniell cells. The solution was not a good conductor.

Sulphate of Iron (Klein's Method).—A solution of sulphate of iron is precipitated by means of carbonate of ammonia; the precipitate is then well washed and afterwards dissolved in sulphuric acid, care being taken to avoid excess of acid. The solution is used in as concentrated a state as possible. It is stated that good reguline metal may be obtained from this solution by means of a current from four weak Meidinger cells, with an iron anode and cathode of copper. In working this solution it is important to prevent it from becoming acid, for which purpose an anode eight times larger than the cathode, or receiving plate, must be used, and a plate of copper or platinum attached to it, so that the two form a voltaic couple in the liquid, and thus cause the iron to dissolve when the current is not passing.

Perchloride of Iron.—A solution of this salt does not yield a deposit of iron. In electrolysing a solution of the perchloride,

Digitized by Google

very carefully prepared, a white deposit was at first obtained, which, upon examination, gave a trace of iron, but a greater portion of the film was insoluble either in sulphuric or hydrochloric acid. The deposit was probably due to some metallic impurity of the peroxide (rouge) employed, but this I have not yet determined.

Persulphate of Iron.—This salt also yields no deposit of iron by elec rolysis. A copper plate became coated with a dark-coloured film, insoluble in either sulphuric or hydrochloric acid, and was probably due, as in the former case, to some metallic impurity of the hydrated sesquioxide of iron employed—though how such a foreign metal could find its way into the precipitated hydrate is a mystery, since it was prepared from an apparently pure sample of jewellers' rouge dissolved in hydrochloric acid and precipitated by ammonia.

(*To be continued.*)

JEHL AND RUPP'S SYSTEM OF CONTINUOUS CURRENT TRANSFORMERS.

In our issue of October 28th we gave an outline of the somewhat remarkable system of continuous cu rent transformers designed by MM. Jehl and Rupp. From the additional details which we are now enabled to present it will be seen that in working out these principles the inventors have introduced several improvements and modifications, some of which tend no doubt to increase the practical value of the system. We must, however, leave our readers to form their own opinion as to the merits of the system, as we have not had an opportunity of inspecting the apparatus ourselves.

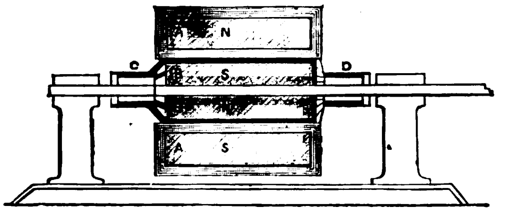

Fig. 1.

In Fig. 1 is shown a longitudinal section of one of these transformers according to the latest design; in this case the "distribution commutator" is done away with. A A represents an iron cylinder wound as a Gramme ring. The sections of the windings are connected to the commutator D, and the brushes bearing upon this commutator are placed in the main circuit which is supplied from the central station with a high tension continuous current. When the ring is rotated its polarity (which may be as shown in the figure) will therefore remain fixed in space, except, of course, for the slight shifting to and fro due to the angular width of the commutator bars.

BB represents a drum upon which secondary coils are wound in the usual Siemens-Alteneck fashion. The sections of this winding are connected with the commutator C seen on the left, and the brushes bearing upon this commutator carry off a continuous current which is employed in the local circuit. The peculiar feature of the arrangement is that the drum is permanently fixed within the ring and the whole rotates together as one piece. The design is therefore precisely similar in principle to the Paris and Scott type of transformer, except that the exciting magnets (the ring) revolve with the armature, while their polarity remains fixed in space. Edison's "rotation transformer" (see *The Electrician*, October 14th, 1887, p. 479) is also based upon identically the same principle, though the details are somewhat different.

The chief drawback to the design obviously lies in the fact that the rotation is not automatic as in the Paris and Scott type, but has to be impressed from some external source. On the other hand, although the output of the machine varies with the velocity of the rotation, yet the power absorbed in driving the shaft is only that required to overcome mechanical friction and, perhaps, some Foucault current effects. In fact, it would be possible to keep the coils at rest, and merely to rotate the brushes.

The "distribution commutator," which we have already described and illustrated, is chiefly of use in cases where a number of rotation transformers are supplied from one sub-central station. A single distribution commutator may then be employed for the whole, and in this case the commutator alone need be rotated, while the transformer remains at rest. The large brushes are connected with the main circuit, and the smaller brushes are all connected with the respective coils of the transformers in parallel. It should be noted in favour of this device that the brushes require no adjustment for lead; they act merely as collectors, and may stand at any point upon the circumference of the commutator. M. Jehl assures us that the commutator is absolutely sparkless in working.

In order to increase the efficiency of the rotation transformers the authors have recourse to a device which, though not new in itself, has never, so far as we are aware, been successfully employed before. It is also probably true that the conditions for its success have never been so favourable as in the present case. This device consists in the employment of an iron conductor for winding the secondary circuit, so as to diminish the magnetic resistance across the ring. Of course, in order to do this, it is necessary to increase

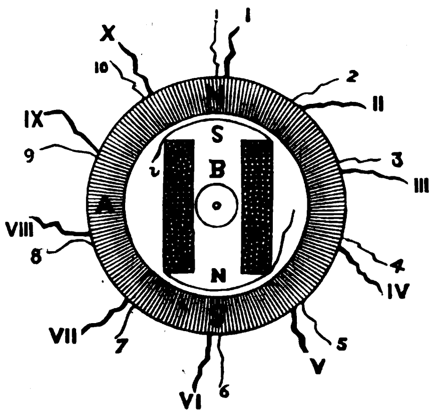

Fig. 2.

the sectional area of the conductor in the proportion of seven to one. In Fig. 1, therefore, the drum is built up of iron cylindrical sectors of exactly the same shape as the bars of a commutator. The cross connections at the end of the drum are made after the fashion of the Edison armature, and must still be of copper to prevent magnetic short-circuiting

By this device the magnetic circuit across the polar diameter of the ring has scarcely any "air gap." There still remain, however, three breaks of magnetic continuity, for the lines have to traverse the primary coils and the central aperture of the drum.

The advantages claimed for the rotation transformer are (1) that it is easier and cheaper to build than the double-wound armatures of the Paris and Scott type; (2) that the insulation between the primary and secondary circuits is greater, and may easily be made very high indeed; (3) that the efficiency is higher owing to the greater magnetic conductivity, and that the rotation of the apparatus as a whole renders it less objectionable for general use.

It will be admitted that the first two claims have considerable weight; but, on the other hand, we have to take into consideration the necessity for using a motor to drive the apparatus. We understand that it is proposed to effect this by means of a small motor placed in the primary circuit. Wherever any kind of motive power is already available this difficulty, however, at once disappears.

The authors have displayed considerable ingenuity in devising a number of modifications in the method of carrying out these general principles. Of these the plan illustrated in Fig. 2 is the most interesting. Here we have a shuttle-wound

Digitized by Google

armature, B, which rotates within a stationary Gramme wound ring. The ring A is wound with two independent circuits (I., II. ... X, and 1, 2 ... 10), connected up to separate commutators. The coil on the rotating shuttle is connected in series with the primary windings of the ring by means of a pair of brushes which bear on two collecting rings; the polarity of this shuttle therefore remains constant. The commutators belonging to the primary and secondary windings of the ring are mounted upon the same spindle as the shuttle; consequently, although the ring remains at rest the polarity of the ring revolves with the shuttle. This arrangement is therefore capable of working as a motor (of the Ayrton and Perry type). At the same time an induced current is generated in the secondary coil, which is taken off from the other commutator.

By suppressing the secondary coil the apparatus works as a motor pure and simple, and this is the arrangement employed by the inventors for driving their distribution commutators.

CUTTRISS'S IMPROVED SIPHON RECORDER FOR SUBMARINE CABLES.

One of the most interesting exhibits at the American Institute Electrical Exhibition is a cable recorder designed by Mr. Charles Cuttriss. The following description of the instrument is taken from the *Electrical World* of New York :—

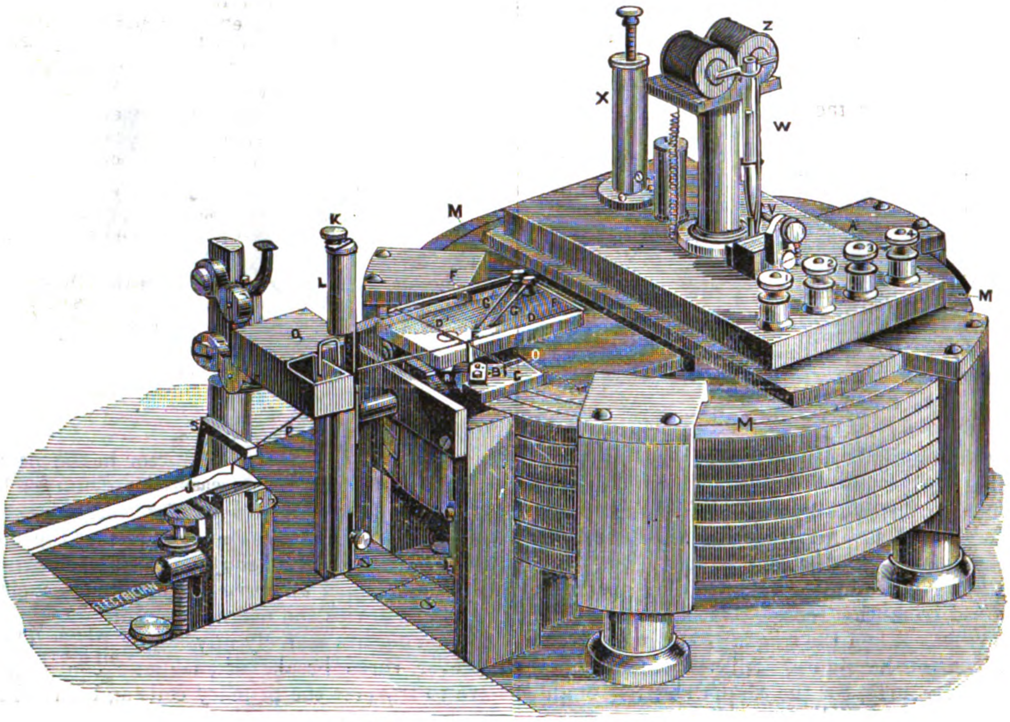
The improvement in this instrument over the older forms consists in the adaptation of magnetism in place of static electricity as a means of maintaining the vertical vibration of the siphon. This vibration is necessary in order that there may be no friction between the marking point of the siphon and the paper slip on which the signals are recorded. The instrument is also more easily adjusted than the older forms, all the adjustments being clearly in view of the operator, so that any desired change can be made in the signals without interruption to traffic. The arrangement is such that, if necessary, the signal coil can be removed and replaced in a few seconds without changing or loosening the fibres or disturbing any other part of the instrument; or the magnets can be removed and replaced without disturbance to the signal coil or its attachments.

The paper slip on which the record is written is drawn at a regular speed under the point of the siphon by a small electric motor placed to the left of the recorder at a distance of about two feet from the siphon. By this arrangement the operator does not touch the slip, but reads and transcribes the signals as they pass under his eye, and he is generally writing the same word that the sender at the distant station is transmitting, instead of being three or four words behind, as is the case with the older forms of recorders, owing to the paper being hidden for some length behind wheel work. This alone effects a great saving of time in the reception of short messages.

The motor has been specially designed to run with six or eight gravity cells, as it has been found that not only are they cheaper to maintain, but they require much less attention than any other kind, and are more easily duplicated.

Our engraving shows clearly the functions of the different parts of the apparatus, of which we will first refer to that part of the instrument appertaining to the vibration of the siphon, and which insures a perfect record regardless of the state of the weather or the humidity of the atmosphere.

The siphon P is a fine glass tube about one hundredth of an inch in diameter, one end of which writes upon the paper slip J, and has attached to its point a piece of No. 30 iron wire about one-eighth of an inch long, which serves as an armature, and is controlled by the impulses of the magnetic table T, over which the paper slip passes. The impulses of the magnetic table are controlled by the vibrator, which is placed on the large permanent magnets M M, and consists of a glass tube W, which is connected by a tube of india rubber to the mercury reservoir X. The glass tube is supported by a steel rod carrying a spring contact point V, and carries an armature, seen opposite the poles of the small electro-magnet Z. When a battery of three or four gravity cells is connected to the terminals 1 and 4, the glass tube commences to vibrate at a rate determined by the height of the column of mercury in the glass tube W, the height of which can be regulated by turning the milled thumbscrew at the top of the mercury reservoir which connects with a plunger within the latter.



Cuttriss's Improved Siphon Recorder.

From the terminals 2 and 3 two wires connect to the electro-magnet of the magnetic table T. Thus, every time the contacts at V are closed the table is energised and the siphon is drawn down to the face of the paper by the attraction of the magnetic table for the small piece of iron which is attached to the point of the siphon. If the impulses given to the

Digitized by Google

siphon are in accordance with its natural rate of vibration a succession of fine dots of ink will be left on the paper in a perfectly straight line, so long as the siphon is not moved laterally by the coil R and a supply of ink is maintained in the inkpot Q. Should the impulses given to the siphon by the vibrator not be in accordance with the natural rate of vibration of the siphon it will not vibrate and the record will fail. But by manipulating the plunger in the tube X the height of the column of mercury W is varied so that the rate of the impulses can be varied anywhere between 60 and 100 per second. Hence any siphon that would be suitable for the instrument can be controlled, as its rate will lie within these limits. When the proper height of the mercury has been once determined, which is generally found in less than half a minute, the siphon will continue to vibrate until it is broken or removed for other causes.

The signal coil R, which is moved by the currents transmitted from the distant station, is pivoted at the bottom and top B in agate bearings, and is free to move in the annular space between the poles of the permanent magnet M. On the top of the coil there is attached an aluminum extension, E, which has a narrow slot at its upper end through which passes the regulating fibre D′, one end of which is attached to a rigid support O, the other end being fastened to a flexible spring F. The strain on this spring and this fibre is regulated by moving the index G′, and the strain thus produced controls the movements of the signal coil R. Close to the point E and at right angles to the fibre L′ there is another fibre D, one end of which is attached to another exceedingly delicate spring F, the other end of which is fastened to an extension from a fine brass wire contained in the tube L, to which the siphon is secured. The upper end of this strained wire is attached to the thumbscrew K, so that by turning the latter the siphon can be moved laterally over the face of the paper to any required position.

Thus it will be seen that if the siphon is moved off the paper slip towards the front of the instrument when the fibre D is strained by moving the spring F outwardly, the siphon can be pulled by it into a position over the centre of the paper; the torsion on the strained wire and the strain on the spring now balance each other, and if the two cross fibres are fastened together at a point as near as possible to the extension E, any movement of the coil will be multiplied and transmitted by means of the fibre D to the siphon. By lifting the fibres out of the slot E and turning the coil toward the front of the instrument the coil and part of the pole-piece C can be removed from the instrument without disturbing any other part, and when replaced no readjustment will be necessary.

THE GOVERNMENT AND THE CHANNEL CABLES.

The *Central News* states that the Government have resolved to keep under their direct control all telegraphic cables between Great Britain and France, Holland, Belgium, and Germany as soon as the present concessions have expired. As far as Holland, Belgium, and Germany are concerned there has been no difficulty. Those countries were ready to readjust their telegraphic arrangements with England, and contracts have already been signed between Great Britain and the Dutch, Belgian, and German Governments, which will, when the present concession expires, place in the hands of the Post Office a monopoly of telegraphic communication. The Post Office authorities have already practically decided to lay additional cables from the East Coast to Rotterdam and Amsterdam, and thus, while a greatly accelerated service will be assured, it is probable that rates will be reduced, provided the International Telegraphic Union consents thereto.

A difficulty, however, has arisen in respect to France, which, after prolonged negotiations, consented to renew the concession to the Submarine Telegraph Company for a further period of fifteen years; but the Postmaster-General vetoed the arrangement, and declined to be any party to the renewal, pointing out that as the Government had agreed to work with Germany, Holland, and Belgium, they could not consent to an independent company dealing with messages from and to France. Moreover, as the British Post Office has a monopoly of all telegraph wires in this country, it would prevent the agreement referred to from being carried out. The authorities, however, were quite willing to buy the cables and plant of the Submarine Company at an electrician's valuation, but they would give nothing for the "goodwill." Against this decision the Submarine Company appealed to the Treasury, and some pressure was brought to bear upon the Government to allow the French cables to remain under the company's management. The French Postmaster-General personally came to London, and is still here. On Wednesday last Sir Julian Goldsmid, the Chairman of the Submarine Company, had a long interview on the subject with Mr. Goschen. The Chancellor of the Exchequer, however, could hold out no hopes of overriding the decision of the Post Office authorities, and little doubt is entertained that the Treasury will grant the necessary funds which will enable the Post Office to accomplish the work. This resolution on the part of the Post Office will, it is anticipated, not only tend towards a vastly improved and probably cheaper telegraphic communication with the Continent, but will also prove to be a profitable undertaking for the Government, as the earnings of the Submarine Company have always enabled them to pay a large dividend. The Post Office is prepared to employ the latest and most approved fast-speed instruments and all modern appliances to ensure the most rapid telegraphic communication between this country and the Continent.

A later report from the same source states that at Tuesday's Cabinet Council the Government finally decided to reject the petition of the Submarine Telegraph Company, and to continue the negotiations with the French Government for direct control over the telegraphic communications between the two countries by their respective Governments.

NOTE ON THE INSULATION OF ELECTRIC LIGHT CONDUCTORS.

M. R. V. Picou, writing in *L'Electricien*, expresses the opinion —in which most of our readers will concur—that the time has arrived when a serious effort should be made to obtain somewhat more definite views as to what ought fairly to be required for the insulation resistance of electric light conductors. M. Picou usefully points out that whatever may be the system of distribution, whether series or parallel, and whatever may be the potential at the terminals of the machine, it is, or should be, possible to express the requisite total insulation resistance in the form

$$R = K r,$$

where R is the insulation resistance, r the copper resistance, and K a constant, which is the one thing we have as yet but scanty knowledge of.

The above expression may be justified by the following considerations :—It will be admitted (though possibly not by every one) that the insulation should increase with and be proportionate to the difference of potential adopted. The *total* insulation resistance must also be inversely proportionate to the total length of the conductors. If the distribution is in series with constant current, then the second condition is included in the first—that is to say, the potential will necessarily increase with the length of the line. If, on the other hand, the distribution is parallel, then the maximum current is a measure of the extent of the circuit. In either case we may therefore write

$$R = K \frac{E}{C} = K r.$$

M. Picou's reasoning is obviously only approximate, for he is obliged to assume that the length of the line is proportionate to the number of "translating devices" which it contains. Nevertheless, on the principle of half a loaf being better than no bread, the expression may be expected to be of some practical assistance.

It remains, however, to get a value for the constant K. Should it be 100, 1,000, or 10,000? For an answer we can only appeal to those who have the means of making measurements of actual installations under various conditions. If some few electricians would devote their spare time to taking measurements of the insulation and copper resistance of all kinds of electric light installations, with careful notes as to the general condition and behaviour of the installation, our knowledge of the coefficient in question would soon be improved.

Errata.—We regret that through an oversight the proof of Prof. Barrett's paper on Manganese Steel, given in our last number, was not sent to the author before publication, and accordingly a few clerical and printer's errors appeared in it; *e.g.*, on p. 545, middle of left-hand column, "intensity nearly eighteen, &c.," should be "elongation nearly, &c." Top of the same page and column (third line) "with the maximum load there was no set," the words "*with the hard wire*" should be inserted; ninth line from bottom of the same column "its increase for temperature," the words "increase for" should be omitted; in the first line of the last paragraph but one from the end of the paper, "more magnetic metal" should be "non-magnetic metal."

"The Electrician" in America.

"THE ELECTRICIAN" *can be obtained in America from* D. VAN NOSTRAND, *23, Murray, and 27, Warren-streets, New York.*

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers. It has the largest circulation of any English Electrical paper, and circulates all over the world.*

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *are prepared to submit estimates for all kinds of Technical Printing—Scientific Papers, New Books, Trade Catalogues, &c., &c.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December next.

The EDITOR *will be glad to receive new names for insertion in the* DIRECTORY *as soon as possible, but not later than December 1.*

All particulars relating to Advertisements will be at once forwarded, on application.

VOLUME XIX.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

Office: 1, SALISBURY COURT, FLEET STREET, LONDON, E.C. (Telephone No. 2714.)

INDEX TO VOLUME XIX.—With our last number was issued as a supplement (Gratis) the Index to Volume XIX. This Supplement should have been received with every copy of the Paper. Complaints of non-receipt should be at once forwarded to the Publisher.

SPECIAL NOTICE.

All correspondence and contributions intended for this Journal should be in future addressed to THE ELECTRICIAN, 1, Salisbury-court, Fleet-street, E.C., instead of to Mr. C. H. W. Biggs, whose connection with the establishment has ceased. We deem it right to add that no other change whatever has occurred or is contemplated in the proprietorship or management of this Journal.

THE ELECTRIC LIGHT AND TRAMWAY AT BLACKPOOL.

The Mayoral banquet given at Blackpool last Friday week was a fitting celebration of a very notable enterprise which reflects the greatest credit on the Corporation and people of that town. It was at Blackpool that one of the earliest attempts at outdoor electric lighting was undertaken, and the lamps erected on the Promenade by Messrs. SIEMENS eight years ago are the same that illuminate it now. Dr. COCKER, the then Mayor, was mainly instrumental in causing the experiment to be tried, and as present Mayor he has commemorated its success in a manner which commends itself best to the civic mind and body. But Blackpool is also noteworthy for one of the most successful applications of electricity to the purposes of locomotion, and at present the solitary example of the "conduit" system in this country. Mr. HOLROYD SMITH's electric tramcar system is perhaps the best known of its kind; and besides being a fairly gratifying success to the promoters it has given great satisfaction to the townspeople. The double event, so to speak, was therefore

Digitized by Google

celebrated with considerable *éclat*; and to import an appropriate tone to the gathering the presence of a number of guests connected with electrical science and industry was duly secured. We are not prepared to say that the electric railroad at Blackpool is "one of the marvels of the universe," or that the fame of "our system of lighting" has extended to the remote Antipodes. On the other hand, we are not in a position to deny that some useful practical work of a pioneer kind has been done at Blackpool; and we are well content that the inhabitants of this interesting watering place should indulge a feeling of pride in their electric tramway. For without the encouragement and assistance given to it by the local authorities, the scheme could hardy have prospered as it really has.

Although it has escaped those disastrous inroads of the sea which on at least two occasions have swept away its prototype at Brighton, the Blackpool electric railroad has had many difficulties to surmount, many mistakes to rectify, and many accidents to make good. If self-help were not a fundamental doctrine in scientific as well as in commercial life with all Englishmen we should almost be disposed to ask for a public grant to cover the losses incurred by experiments of this kind. It is impossible to foresee and guard against every obstacle that may arise in giving practical expression to a promising idea; yet, unless these risks are incurred, the idea can never be realised, and the world is that much the poorer in consequence. As a rule, the first attempts at realisation are failures, and those who direct them are not the people who reap the reward. All the more, therefore, is a debt of gratitude due to the pioneers of electric locomotion, which, like steam locomotion in its earlier development, has so many mechanical and financial difficulties to encounter, that no amount of success to be reasonably anticipated for some years to come can relieve us of our obligations. One of the speakers at the banquet, speaking in enthusiastic terms of Mr. HOLROYD SMITH'S achievement as "a feat which would not be forgotten," added "Blackpool would figure prominently in the history of electricity when it came to be written." That may be a pleasant outlook for Blackpool; but for the men who risk their money and reputation on novel and untried enterprises the prospect is not so satisfying and the tangible result not so alluring.

Nevertheless, the promoters of electric locomotion have succeeded far beyond what is customary in such ventures; and the one at Blackpool affords promise of a not very distant future which may recompense them for all the disappointments and struggles they have had to brave. From November 1st, 1885, to the end of October in the following year the electric tramcars at that place ran 70,492 miles, carrying 636,252 passengers. With the exception of a six days' stoppage, through frost and sand, last winter, the railway ran continuously till Whit-week of the present year, when a serious obstacle arose, in consequence of the continuous hot weather, which expanded the copper tubes, so as to drag the iron stud of the insulator, which had corroded and got loose by the action of the salt water. Notwithstanding the delay caused by these unforeseen accidents, the number of passengers carried during the year just ended has been nearly as great as in the preceding year; and at the present moment the line is working as well as can be wished, the machinery and general arrangements being now in a better condition than they ever were. It would be rash for even a native of Blackpool to assert that the whole problem of electric railroads has been solved by this very admirable experiment; but it certainly affords much ground for confidence in the future prospects of that mode of locomotion. It was but natural under the circumstances that a good deal of tall talk should be indulged in, and visions of electric motors supplanting the steam locomotive and running with double express speed at half the present cost. But for the present we are more disposed to follow the speaker in his reference to the superiority of electricity for the underground railways of the metropolis—a superiority which we have reason to believe may yet be demonstrated at an earlier date than most people imagine.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

The following circular has been addressed from this office to the Electrical Engineering firms throughout the country:—

DEAR SIRS: With reference to the present discussion on the advisability of forming an association to deal with the commercial aspect of electrical engineering, it has been suggested that the editors of this journal should take the initiative in arranging for a meeting of the trade. Before undertaking this responsibility, and solely in order that a public discussion of the question may lead to some definite result, for or against the proposal, we have thought it desirable to submit to you certain suggestions which have been made, in the form of a series of resolutions, for consideration at the proposed meeting.

It will, we trust, be understood that in taking this course our object is to facilitate discussion, and not to direct the organisation of the movement—a duty which must rest entirely with yourselves, or with such Organising Committee as you may appoint.

May we therefore trouble you to return the annexed sheet, signifying thereon your assent to or dissent from the Resolutions proposed, and to add such suggestions or modifications as you may prefer? As soon as these replies have been received the results will be published in *The Electrician*, and should they be of such a character as to justify further action, you will then be invited to attend a public meeting.

Faithfully yours,

THE EDITORS OF "THE ELECTRICIAN."

RESOLUTIONS.

I.—That this meeting recognises the desirability of forming an Association for the discussion of matters relating to the Electrical Industries, and for securing the united action of the representatives of those Industries where their commercial interests are in general concerned.

II.—This meeting further recognises that the existing SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS is entirely capable of fulfilling the scientific requirements of the Electrical Industries, and that the proposed Association should supplement without superseding in any degree this or any other existing Institution.

III.—That an Organising Committee of twelve members (with power to add to their number) be now nominated from the body of this meeting.

IV.—That it be an instruction to the Committee to consider the details of the scheme, and in particular to report on the following points:—

(1) The practicability of working the Association on the basis of holding two half-yearly meetings, each (say) of three days' duration.

(2) On the conditions of membership.

(3) On the financial aspects of the scheme.

We shall be glad to send this circular to any firms who, through inadvertence or the incompleteness of our lists, may not have received a copy.

We select the following letters for publication this week as representing more exactly the views which we ourselves have entertained on the subject from the very first:—

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Judging from the correspondence and from some other printings on this subject, it appears that the real objects of the Association are being misunderstood. I do not know that I am right, but I was certainly under the impression (1) that

Digitized by Google

as electrical developments have increased so enormously in the past few years; (2) that as electrical applications have in so many ways called for the combined skill of the electrician and mechanical engineer; (3) that as electrical engineers are practising in a comparatively new field and on an untrodden path of engineering enterprise; (4) that as electrical manufacturers are working for and establishing a new industry; (5) that as these manufacturers have to work to a great extent to suit the electrical engineers, and the latter in accordance with manufacturers' exigencies, and as both electrical engineers and manufacturers have to work in connection with steam and other engine builders; and (6) that as there are so many questions upon which these several sets of men could, for these several reasons, meet with advantage to compare notes, discuss practical problems that turn up from time to time, questions of policy, and subjects requiring concerted action, an Association of Electrical Engineers was deemed necessary. It is well known that there are many busy men who have not the time to spare to sit down to write systematic papers on questions in electrical engineering practice or enterprise, but who could, at the meetings of a suitably organised association, present such subjects in the remarks of a few minutes.

The experience of the more active part of the life of the Dynamicables showed that very useful debates on practical questions could be obtained in this way, the proposed subject of debate and the name of the proposer and propounder being given in the programme sent out announcing the meeting. Most of the members of the Dynamicables are members of the Society of Telegraph-Engineers or the Civil or the Mechanical Engineers; but none thought that the Dynamicables were Trades Unionists on the one hand, or met to conspire against these older societies on the other. The questions that do and will crop up on electrical engineering matters are so very numerous that more than one existing society will have to double the number of its meetings, extend the scope of its discussions, and relax some rules concerning papers to be discussed if they intend to avoid the necessity for a special society. The purely trade notions which have been disseminated concerning the proposed society are, I assume, mistakes, and that the real object is to form a society for the advancement of electrical engineering and manufactures, and generally for the advancement of the interests of those engaged in the practical applications of electricity.

London. W. W. B.

SIR: The idea to form an Electrical Association in England has taken its origin from the fact that something of this kind exists in America, and may therefore be found very useful in this country.

Allow me to say that the American Association is based on a state of matters totally different from that existing here. The men who are interested in the various central stations located in almost every city of the United States felt a desire to meet twice a year for the purpose of exchanging their views and experiences. These meetings are at the same time visited by manufacturers, who avail themselves of the opportunity to demonstrate and exhibit new devices for the purpose of supplying electric light and power from central stations. The various Edison companies are not members of this association, but hold their meetings separately.

What is wanted in England is something entirely different. Electric light stations hardly exist, but the electric light business meets with difficulties which are quite peculiar to this country. An association formed for the tangible purpose of dealing with these difficulties would undoubtedly have the hearty support of all members of the profession, and of all those interested in the use of electric light and power.

We do not require another discussing society such as the Society of Telegraph-Engineers and Electricians, nor an electric light police which has to watch over the prices charged by different contractors; but an association formed for the purpose of accomplishing the first three objects mentioned in Mr. Rawson's letter, excluding the other fourteen, would probably find general support.

If after a series of years this "Electric Light and Power Association" has fulfilled its object it may well go to rest with the feeling of having done something useful, or it may later on extend its objects in order to meet the wants of some future time.—Yours, &c., ALEXANDER BERNSTEIN.

REVIEWS.

Handbuch der Elektricitat und des Magnetismus. By Dr. O. FRÖLICH. (Berlin: Julius Springer.)

This handbook of electricity and magnetism is a second edition of a work published under a different title nine years ago, and is intended to bring the original work up to date. With this object considerable additions have been made to the first edition, which was a handbook of telegraphy; but the result is not altogether satisfactory. The portion of the present work treating of telegraphy is good. The author has evidently considerable experience in this particular branch of applied electricity, and he has succeeded in explaining the somewhat complicated phenomena occurring in long submarine cables with great clearness, and, as far as could be done with the exclusion of mathematics, even with scientific accuracy. But if we turn to the remaining portion of the book—which is professedly written as a guide for electricians engaged in the construction and use of dynamo electric machinery and telephonic apparatus—we cannot pass such a favourable verdict; in fact, it is difficult to see what class of readers is to derive practical advantage from this book. In form it resembles somewhat an ordinary elementary science text book, but without rigorous scientific treatment, whilst its substance—in these days of rapid development in all branches of applied electricity—is really very slender and stale fare. The practical electrician will not find in this book any information about the most modern dynamos, motors, lamps, &c., whilst the schoolboy, who might take the book up with the object of studying the science of electricity as taught by one occupying a high position in the profession, will find his study uselessly burdened with descriptions of the early dynamo machines made by Messrs. Siemens and Halske, of Berlin, the early arc lamp (by the way, the only arc lamp described in the book) made by Messrs. Siemens and Halske, of Berlin, the various and mostly antiquated alternate current dynamos made by the same eminent firm, and so on. The description of a few machines and instruments made by the firm with which the author is connected does not suffice to give the book a practical value, whilst the omission of all mathematical treatment beyond simple algebra, and especially the omission of the theory of the potential, seriously diminish its scientific value.

We have already said that the chapter treating of telegraphy is well written and will be useful to telegraph engineers. The author discusses at length the insulation resistance of long submarine cables; the counter electromotive force observed in a cable, which he considers as probably due to molecular strains in the insulator; the capacity of cables; the retardation and weakening of currents; the induction in overhead lines; the speed of propagation of electric waves in cables and wires, &c. The chapter dealing with electric measuring instruments and their application to the finding of faults in telegraph lines is also of value, but we regret that the author should in the main have restricted his descriptions to apparatus made by Messrs. Siemens. The reason for this restriction is stated in the preface, and as it is characteristic of the self-sufficiency of a certain school of modern German technical *savants*—of which class the author is by no means an isolated example—we make no apology for giving here a verbal translation of the passage:—"As regards measuring instruments, these described are almost exclusively made by Messrs. Siemens and Halske. I hope that this will be found but natural, since I have for a considerable time cultivated this branch of the firm's business, and since it cannot be considered one of the duties of an author to prefer the opinion of others to his own."

THE DESMAZURES SECONDARY BATTERY.*

BY M. E. REYNIER.

The well-known zinc-potash-oxide-of-copper cell of MM. Lalande and Chaperon is excellent as a primary battery; but, although these inventors have made many attempts to regenerate the cell by electrolysis, their efforts have not led to industrial success.

A secondary battery of this description—that is to say, employing caustic alkali in lieu of acid—has, however, at length been produced by M. Desmazures, and has recently attracted some attention amongst electricians by its performance at Havre, where a battery weighing 4,400lb. propelled a launch weighing 11,000lb. during five hours at the average speed of 6·5 knots per hour, the output being at the rate of 12 horse-power, or a total of 60 horse-power hours.

The negative plates of this cell are made of tinned iron; the positives are plates of porous copper, obtained by compressing the pulverised metal under 600 to 1,200 atmospheres. The liquid is a solution of zinc in sodic hydrate, or a solution of potassic hydrate added to chlorate (?) of sodium. The cell is made of tinned iron; it is entirely closed in, and is connected with the negative plates.

During the process of charge metallic zinc is deposited, and is taken up in solution during discharge. The oxides of copper are not completely insoluble in the caustic alkalis. In order to avoid the solution of the oxides in the electrolyte, and their reduction upon the zinc, the positive plates are enclosed in bags of parchment-paper supported by vertical rods of glass, which also serve to insulate the plates. The following figures relate to a cell of type No. 4:—

Number of positive plates		5
,, negative ,,		6
Total weight of plates		13·2 lb.
Size of positive plates	height	0·25 in.
	breadth	0·25 ,,
	thickness	0·002,,
Size of negative plates	height	0·3 ,,
	breadth	0 25 ,,
Total weight of cell		44 lb.
E.M.F. on open circuit		1 volt
External E.M.F.		0·85 ,,
Charging current		18 amperes
Maximum discharging current		36 ,,
Capacity		372 amp. hours
Work done in discharge		0·42 h.-p. hour
Weight of plates per h.-p. hour		66 5 lb.
Total weight ,,		99·5 ,,
Weight of plates for h.-p. (output)		323·5 ,,
Total weight ,, ,,		1078·0 ,,

But the battery employed in the Havre experiments seems to have shown better results than these as regards weight. The battery of 132 cells weighed 4,400lbs. It gave during five hours a current of 87 to 89 amperes under a potential of 100 to 104 volts. We thus get:—

Total weight per H.-P. hour	72·6 lb.
Total weight for one H.-P. (output)	365·5 ,,

A considerable reduction of weight has thus been effected, but on the other hand the available E.M.F. has fallen to 0·78 volt per cell.

But the weight of 365·5lb. per horse-power is not remarkable; it had already been obtained—*upon the same boat*—by Reynier accumulators with corrugated plates, in November last year. But for ratio of work (horse-power hours) to weight, the Desmazures cell is superior to any Planté cell as yet in the field. It is also claimed that the cell has a very high coefficient of restitution. *A priori* it may be admitted that this will be the case as regards the ampere-hours, because the electrolysis of alkaline zincates is not accompanied by the evolution of gas, and yields deposit of zinc of very regular and very adherent character.

But, on the other hand, we have to remember the loss of E.M.F. In my own experiments I have found that while it takes an E.M.F. of at least 1·2 volt per cell to charge this type, we do not get more than about 0·65 volt in the discharge.

The duration of the negative plates will no doubt be very great in this cell, as in all others. As to the positives I am not so sure. The flakes of greenish blue are not reassuring; the parchment paper will certainly be attacked by the caustic alkalies. The inventor should amend this detail.

Comparison of the Caustic-Alkali Cell with the Planté type. Should the relative lightness of the caustic-alkali cell induce us to abandon the Planté type? What is the probable future of the two systems?

While waiting for an answer from practice we may interrogate theory, and we shall learn that *in principle* the Planté type is preferable to the other, *even in point of view of lightness.* Let us compare the weights required in the two systems for the same output, for example 3,600 kilogrammetres.

PLANTÉ TYPE.

Available Difference of Potential 1·8 Volt.

	Grammes.
Lead	42·21
Oxygen	3·26
Sulphuric Acid	20·00
Water	40
	105·47

CAUSTIC ALKALI TYPE.

Available Fall of Potential 0·8 Volt.

	Grammes.
Zinc	15·1
Cuprous oxide	18·3
Potassic hydrate	25·7
Water	77·1
	136·2

Theoretically, therefore, the Planté cell is lighter by 23 per cent.

The actually lightness of the Desmazures cell is due to a better utilisation of the essential elements. The excessive weight of the lead elements is above all due to the mass of inert metal which acts merely as a conducting support for the active material. If this dead weight could be suppressed or diminished it would make a surprising difference. I have myself obtained remarkable results in this direction, but to avoid introducing the personal element let me be content to refer to the plates of Mr. FitzGerald which are exclusively composed of lead peroxide, with a thin conducting plate of platinum. These cells are said to answer very well, and they give a horse-power-hour with a weight of less than 73lb.

It seems, then, not difficult to realise in practice the theoretical superiority of the Planté cell in the matter of weight. We ought also not to lose sight of the fact that the lead cells occupy much less space than the other type. This is frequently an important point.

In the matter of first cost it is necessary to remark that copper and potassic hydrate are more expensive than lead and sulphuric acid. In fact, in combining the figures for theoretical weight and cost of material for the same output, we find that the first cost would be about four times as great for the alkali as for the acid cell.

* From the *Moniteur Industriel*, November 3rd, 1887.

NOTE ON TRADE DISCOUNTS.

BY J. M. V. MONEY-KENT.

The writer feels that some apology is needed for this note, as the problem involved is of the easiest possible description; but yet, finding it to be an almost universal practice to employ a happy-go-lucky method for its solution, he ventures to give the following solution as being quite as easy as any haphazard method.

To find what percentage it is necessary to add to a given figure in order to allow a discount of a given amount:—

Digitized by Google

Let x = the given figure,
X = the new amount,
λ = the percentage to be added,
μ = the discount.

Then we have

1. $$x\left(1+\frac{\lambda}{100}\right)=X$$

2. $$x = X\left(1-\frac{\mu}{100}\right)$$

The elimination of x, X is at once given by the determinant.

3. $$\begin{vmatrix} 1+\frac{\lambda}{100}, & 1 \\ 1, & 1-\frac{\mu}{100} \end{vmatrix}=0$$

the solution of which is

$$\lambda=\frac{100\,\mu}{100-\mu}.$$

By writing this in the form $\frac{\lambda}{100}=\frac{\mu}{100-\mu}$ a simple rule of thumb method is at once obtained, for $\frac{\lambda}{100}$ represents the fraction of x to be added. Thus, if the discount to be given be $\frac{a}{b}$, then the amount to be added will be $\frac{a}{b-a}$.

If we go one step further we may represent the whole thing by means of a curve, and such a curve traced out with ordinates and corresponding abscissæ marked and hung up would be very useful in the office as a reference table. Putting $x\ y$ for $\lambda\ \mu$ in equation 3, and expanding, we have

$$x\,y-100\,x+100\,y=0,$$

which is the equation of an equilateral hyperbola passing through the origin whose centre is given by the equations

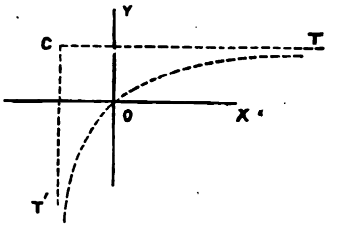
$$x+100=0$$
$$y-100=0.$$

Also $$\frac{dy}{dx}=\left(\frac{100}{x+100}\right)^2.$$

Hence $x+100=0$ is an asymptote; similarly $y-100=0$ is an asymptote, and the axes are given by

$$x^2-y^2+200\,(x+y)=0.$$

Thus the curve is easily traced, and is as follows:—



C is the centre of the curve; C T, C T', the asymptotes. Thus the ordinates represent the discount it is intended to allow, and the abscissæ the percentage to be added.

SPUR GEARING FOR ELECTRIC TRAMCARS.

Mr F. J. Sprague, whose electric motor system is well known in the United States, writes as follows to our contemporary, the New York *Electrical World*:—

At a meeting of the American Institute of Electrical Engineers, held September 20th, Mr. Anthony Reckenzaun, in an address on the subject of "Electric Street Cars, with Special Reference to Methods of Gearing," referred to the experiments which are going on at Mr. William Wharton, jun.'s establishment in Philadelphia, and makes the following statement:

There we used a set of spur gearing, which was supplied by the Sprague Company. In this case the motor shaft, which runs at from 500 to 600 revolutions a minute, carries two steel pinions, one at each end of the shaft, and these pinions gear direct into two cast iron spur wheels upon the driving axle without any intermediate wheels. The motor is partly suspended on the axle and partly on the body of the car. We have run several hundred miles with this car under all conditions of load, gradients, and weather, on some of the roughest tracks in Philadelphia, but up to this moment not a single hitch has occurred. The gear is perfectly noiseless, it is efficient and strong, and I see comparatively little indication of wear. The teeth are beautifully shaped, therefore somewhat expensive; but if they last long enough and if they do not rattle when partially worn, this expense can be ignored. This car contains, besides its usual weight, about 3,200 pounds of storage batteries. It has to mount grades of 5 per cent., and run on curves of 35 and 25 feet radius, which means very hard work.

I wish to correct an impression which one would gather from these remarks of Mr. Reckenzaun, and which hardly do justice to the method of mounting which is there used. The suggestion that the gears are necessarily expensive because of the beautiful shape of the teeth is incorrect; the shape of the teeth has absolutely nothing whatever to do with the expense of the gears as we make them, for they are no more expensive than any other form of tooth in cut gears.

There are several reasons other than the shape which make these gears so noiseless. The motor, in the first place, is hung upon the driving axle at two widely distant points, and is supported in the centre of the other side by a double compression spring. In this manner absolute parellelism is maintained between the driving and the driven axle in all planes, no matter what the movement of the axle. There is no twisting or tendency to twist on the face of the gears and pinions; the thrust at all times is absolutely in the plane of the gears and pinions, and these are always parallel. The bearings of the armature are very close to the pinions, so that there is no spring whatever in this shaft. One pinion is set about half a tooth ahead of the other. One of the main gears is fixed; the other is adjustable, so that there is no interference in the thrust of the pinions, and a much more perfect simultaneous meshing of the gear is obtained than would be possible where dependence upon the cutting of the splines is necessary for the adjustment.

From two to three teeth on each pinion are always engaged. The proportions of the pinions are such that the armature has to make as many revolutions as there are teeth in the large gear before the same teeth in the gears and pinions engage with each other, and, finally, by reason of the method of supporting, there is always a spring touch, so to speak, of the pinions upon the gears. No matter how sudden a strain is brought upon the motor, it always yields more or less in a direction concentric to the axle of the car, so as to relieve the teeth from all shock. The wear of the gears must be absolutely the same. It is simply impossible for rattling to take place on these gears even if they were worn down one-half of their present thickness, and this wear, where the gears are properly protected by screens, will be very light.

The method of mounting and the general plan of using these gears has far more to do with their noiselessness and efficient operation than the shape of the teeth, although this shape, being of the involute character, is such that they will mesh perfectly even where there is some change in the distance between the centres of the axles. If it were not for the method of mounting it would be impossible to run this kind of gearing, as has been frequently done, with variable strains at a speed as high as 1,200ft. per minute. At no time, under the severest strains it is possible to put on gears of this character, have they ever shown any signs of weakness or undue wear, and in comparison with fixed gear this method of mounting must necessarily be the more satisfactory.

BANQUET TO ELECTRICIANS AT BLACKPOOL.

We briefly referred in our last issue to the banquet given by the Mayor of Blackpool in connection with the electric traction and arc lighting carried out in that town. The speeches of Mr. Alexander Siemens, Mr. Parker, Mr. Broadbent (of the Tramway Company), and Mr. Chew (the engineer to the Blackpool Corporation), which we print below, will be read with interest:—

Mr. Parker, of Wolverhampton, in responding to the toast, said that electricity as used for locomotion had a very short history, and most of them would be acquainted with it as applied in this respect. Many would remember seeing at the Paris Exhibition of 1881 perhaps the first tramway of any importance that had been publicly exhibited. Many of them would have visited the tramway at Portrush, in the north of Ireland, one of the first and still perhaps the longest in use in this country run by electricity. They at Blackpool followed, and perhaps succeeded in doing a greater work, which it would not have been to their credit if they had not done. He was glad to hear strangers speak well of the enterprise, because the Blackpool tramway was now old—two years in the history of electrical development was a long period of time. When they looked and saw what had been done on the Blackpool tramway, and considered what could be done they thought that this enterprise was but a small dwarf as to what was possible and practicable. He remembered that when they first tested the motors now driving these trams they found they could get 7 horse-power with about 16 hundredweight in the motor. They could to-day easily obtain 25 horse-power from the same weight, and at the same time attain a higher state of efficiency. They could now at half the cost produce better machines than the dynamos now used for the Black-

Digitized by Google

pool tramway. He did not say this to discourage the Blackpool people, but he felt bound to give exactly the circumstances as far as he conceived them. They had got on to a period of further development and application of electricity, and could to day drive electrical tramcars by storage For a long time the gearing of tramcars stood in their way, but the gearing had been simplified and rendered more practical and controllable in the driving of cars. He had taken a contract to put a motor on the tramway at Wolverhampton which would enable the cars to run by storage up a gradient of 1 in 18, and to run a length of 7 miles and carry 50 passengers. There was at present an agitation with regard to underground railways. Electricity was extremely well suited for driving underground trains. With electricity they could get rid of the nuisance of smoke and noxious vapours in underground carriages. He considered from past experience that no limit seemed possible to the application of electricity as a driving power, and almost whatever was asked of the firm of which he was a representative they were prepared to carry out. He believed that by electricity a train might be run from London to Edinburgh at a speed of 70 miles an hour cheaper than by steam. He was not in the habit of prophesying, but he spoke only from facts, and believed the time had arrived when almost anything desirable could be achieved by electricity in its application to railways [applause].

Mr. BROADBENT said he was much disappointed with the speech of Mr. Parker, the gentleman who supplied their machinery, for he now told them that he could supply it at half the price [laughter]. As to Mr. Parker's confidence in accumulators, he could not yet share that confidence. Accumulators were at present on paper, and paper would not pay dividends. As they were aware, a little over two years ago the Mayor of Manchester (Alderman Harwood) did Blackpool the bonour of inaugurating its electric tramway. He drove the first car, and afterwards spoke confidently of the line's future success, and at the banquet which followed, Mr. Holroyd Smith, the patentee of the centre channel, explained the theory of its working. However, the few remarks he (Mr. Broadbent) had to make were on the results. For over two years they had had many difficulties to contend with. They found that the motors for the cars were not quite equal to the strain put upon them; but, by the kind assistance of Mr. Parker, the maker of the machines, these had been very much improved. The collectors also gave much trouble, mainly through the shallowness of the channel, but by experience they had been able to overcome this difficulty to a very great extent. Had the centre channel been made deeper many of the troubles would have been avoided, and the expense of cleaning the channel very much reduced. In his opinion, if their system of tramway were laid where there were not the difficulties of sand and sea-water to contend with, and constructed with a deeper channel, it would prove a great success. From November 1st, 1885, to October 31st, 1886, they ran 70,492 miles and carried 636,252 passengers. The cars were stopped for five or six days, the stoppage being caused by frost and sand. The working continued very satisfactorily until shortly after Whit-week in the present year. Then the continuous hot weather caused the copper tubes or current conductors to expand so much as to drag the iron stud of the insulator, which had corroded through the contact with salt water, until it had become loosened. This caused a leakage and the insulator to crack. They expected to overcome this difficulty as they had overcome many others, as they had got a new insulator on an improved principle that they thought would be effective. This accident had caused a serious loss to the company which could not be avoided. However, he did not expect such a misfortune to happen again. Notwithstanding this stoppage they ran between November 1st, 1886, and October 28th, 1887, 72,875 miles, and carried 619,500 passengers. At the present time the working was as well as could be wished and the machinery in excellent condition. They were able to carry six times the amount of passengers they could get in the winter months without additional cost to the Company. Many people had said that they should never succeed, but he thought the figures he had quoted would prove that they had run fairly well, and augured well for the future.

Mr. SIEMENS paid a cordial compliment to the enterprise shown by Blackpool people. He thought, with Dr. Kingsbury, that electric lighting should be extended to the houses. This was the second time he had visited their town, his first visit being on the occasion of the introduction of the electric light, eight years ago. He was glad to see that the lamps which were then arranged, and which had been since that time under the good care of Mr. Chew, did not compare badly with some of the more modern lamps [applause]. It would be difficult to appreciate the public spirit shown at that time by Blackpool, because we progressed now so quickly that one was apt to forget the position of affairs in 1879. The electric light had just been talked about, but nobody appeared to know anything about it. Their present mayor came up to London to see him, and said they wanted their Promenade, the distance of which he believed was 2,700 yards, lighted by electricity. Such lighting had not been done at that time, and his firm would never have had the opportunity of carrying out such lighting had it not been for the public spirit and enterprise shown by Blackpool. That the system which they adopted succeeded was due to Sir William Siemens, whose loss they all deplored [hear, hear]. Its success also was very creditable to Mr. Chew, who had managed the undertaking exceedingly well from a financial and also from an electrician's point of view. Blackpool, he thought ought to feel proud with such an enterprising Corporation and such a skilful engineer [applause].

Mr. CHEW said that power to carry out the Blackpool line was obtained from Parliament in 1879, a clause being inserted in the Improvements Bill by which they were enabled to supply electricity for public purposes. These clauses were put into most of the Acts obtained about then by the Parliamentary agents. So far as the Blackpool Corporation was concerned, an additional clause was put in that gave power to borrow £5,000 to be used for electrical purposes. This was only obtained on condition that the whole was to be repaid in ten years. This clause was a very heavy burden upon the past and present ratepayer. Nevertheless, three-fourths of the sum had been paid, and the balance would be paid off in 1890, after which the apparatus at present in use would be the clear property of the ratepayers without further charge, except for wear and tear. The present mayor, who was also mayor at that time, had determined, in conjunction with the Council, to make a forward step, and, if possible, to add to the attractions of the three miles of Promenade by lighting that part situated between the two piers, and also at the pierheads, with the most powerful of the then-known arc lamps. He need not say with what result, as that was known to them all. They now possessed the best display at night on the Promenade in the visiting season that could be found in England. The area between the piers had 54,000 candle-power of arc lights, the other portions of the Promenade having double-burner gas lamps—one at every twenty-five yards—covering the whole distance. These arc lights were a great convenience to the numerous pleasure steamboats that sailed between there and the Isle of Man, Llandudno, Wales and the Lake District. The lights could be seen out at sea from the packets for fully fourteen miles. In the earlier period they had considerable difficulty in dealing with the electric force. Leakage, as every electrician knew, was the bugbear constantly to be contended with; expansion and contraction of the wires, faulty packing and insulation, delicacy of the machines and instruments, rendered constant and skilled supervision necessary. But experience had been gained, and that counted for something in the general result They had seen that night some of, if not the very best arc lamps at present in use. It might be interesting to show what had been the cost, both on capital and maintenance account, and for that reason he had taken out the items of the maintenance account for the last five years and classed them under different heads. To begin with, the capital expended was £3,600—for machines, wires, engines, boilers, lamps, posts, sheds, and cost of erection. The interest of this, at 5 per cent., is £180 per annum, and for the five years would be £900. They used the lamps only 1,000 hours each year, or, for the five years, a total of 5 000 hours. That worked out to be 3s. 9d. per hour for capital charges at the above rate of interest, but, of course, they paid considerably more in consequence of having to repay the principal in ten years; yet they had been maintaining the plant for the last eight years in first-class order, nearly all the wires and posts having been renewed and the wire put underground. The boiler tubes had been renewed, the whole plant being in some respects improved, in other respects remaining as good as at first. For the wear and tear for the five years—representing 5,000 hours of work—the account was as follows:—

	£	s.	d.
Fuel, water, gas, oil, &c.	£473	19	4
Carbons	389	4	2
Wages and salaries	845	10	11
Repairs and renewals (including wire)	863	19	3
Rent of ground	45	0	0
Rates and taxes	69	5	5
Boiler insurances	15	15	0
Carriage and sundries	42	10	9
Experiments	21	14	8
Total	£2,767	19	6

That worked out to 11s. 1d. per hour, which added to the 3s. 9d. made a total of 14s. per hour for a light nominally of 54,000 candle-power, and he knew from practical tests that these lights did give an average of from 4,000 to 6,000 candle-power each for the nine lamps in use [applause].

CORRESPONDENCE.

PRIMARY BATTERIES FOR HOUSE LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the discussion which followed the reading of Mr. Perry Nursey's extremely interesting paper "On Primary Batteries" before the Society of Engineers last Monday, we were favoured with the usual professional comparison between the cost of coal and that of zinc, with the seemingly inevitable inference, inseparable from such discussions, of—"*Ergo*, primary batteries cannot possibly compete with dynamos and steam engines." A few figures will, however, suffice to prove that such an inference is quite erroneous.

1st. When burning coal, even at the low rate of 4lb. per horse-power per hour, a steam engine is only utilising less than one-sixteenth part the theoretical heating power of the coal, for 1 horse-power (as defined by Watt) is equal to 33,000 foot-pounds per minute; whereas the theoretical power of 1lb. of coal is 10,500 (heat units) × 772 (Joule's equivalent) = 8,106,000 foot-pounds, and $\frac{4 \times 8106000}{60 \times 33000} = 16{\cdot}37$, a formula which to most of your readers will be perfectly familiar.

2nd. At 17s. per ton, one penny will purchase rather more than 18lb. of coal, so that the value of the 4lb. of coal is $\frac{2}{9}$ths of one penny. How is it that the theorisers do not go a step further and explain that their comparison of the cost of primary batteries with dynamos worked by steam or gas and accumulators would only hold good if the entire cost of that combination were represented by this $\frac{2}{9}$ths of one penny per

Digitized by Google

hour, or, say, twopence for the average lighting day of five hours? The wages of one mechanic to attend to the engine and dynamo, keep in order and renew the brushes, &c., amount alone in small installations to more than the whole cost involved in the use of a primary battery; moreover, one horse-power per hour produced from a steam engine does not supply anything approaching one electrical horse-power of 746 watts. At the South Kensington Exhibitions the engines practically supplied on the average less than half that quantity of electricity in the lamps. The same is produced from one pound of zinc, costing 2d., working noiselessly, steadily, and without any attention in a primary battery.

3rd. With regard to gas, one ton of coal makes 10,000 cubic feet, and at 3s. per 1,000 cubic feet, costs the consumer 30s. Then, 4lb. of coal, converted into gas, produce eighteen cubic feet, which, with gas of 15 candle-power, will give light equal to fifty-four candles when burnt in the "London Referee" Argand burner. The ton of zinc costs eleven times as much as 30s.; but, on the other hand, 4lb. of zinc in a primary battery supplies 1,490 watts (two horse-power), or sufficient electrical power for twenty-four lamps of 20 candle-power (each of 62 watts), or 480 candles, and, weight for weight, nearly nine times as much light as that obtained from 4lb. of coal converted into gas and burnt under the most favourable conditions.

These figures, which any of your readers are quite competent to check, conclusively disprove the *à priori* contention that the question of the applicability of primary batteries to house-lighting is disposed of by the comparative cost of zinc and coal. Questions of mechanical detail, compactness of form, quantity and constancy of current, and, above all, the reduction of trouble to domestic servants, by simple arrangements of manipulation, are points of more importance; but, judging from my own experience, none of them appear to be such as need stand in the way of the future employment of primary batteries as the solution of the question of house-lighting by electricity.—Yours, &c., O. C. D. ROSS, M.Inst.C.E.

15, Relf-road, East Dulwich.

THE PURCHASE OF THE EDINBURGH GASWORKS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I send you a copy of a letter which I wrote to the *Scotsman* – but which the editor would not publish—upon the proposed purchase of the gasworks by the town, which the *Scotsman* is desirous should be effected immediately. I also send you extracts of other letters against the scheme which they have seen their way to insert, and which of course they had no difficulty in replying to.

As this is typical of the vested interests against which electric lighting has to combat, as well as an example of the method adopted of upholding the same, it may afford interest to you and your readers.

The town authorities propose to pay the shareholders of the gasworks a 10 per cent. annuity on the value of shares, for the purchase—that is, equivalent to a capital sum of over £600,000 for what they might get for considerably less in ten or twenty years' time.—Yours, &c., W. GEIPEL.

6, York-place, Edinburgh, November 8th, 1887.

[COPY.]

To the Editor of the "Scotsman."

SIR: It may be of interest to your numerous readers to hear that during the few years I have been resident in Edinburgh, representing a well-known electric light company, we alone have either put to work or in course of erection a considerable number of isolated electric light installations, and from a knowledge of the amount of gas previously consumed in the various establishments, I find the total yearly consumption of gas superseded by electricity to be approximately equivalent to a revenue of £1,500. I see no reason why this progress should not be continued. Setting aside future inventions, it is my opinion that electricity, unfettered as it now is by such an Act as the Electric Lighting Act of 1882, is even now a not insignificant competitor of gas, not only for the illumination of our theatres, railway stations, works, and factories, but also in the homes of the more wealthy inhabitants. and in better-class shops, &c., while, for the supply of power to small users, such as printers, small workshops, and the like, electricity has, in Continental towns, wherever it can be had from the street mains to drive motors, proved itself in every way better fitted than gas engines. In the United States there is hardly a town of 20,000 inhabitants and upwards which has not a central station for the supply of electricity, and many also of from three to four thousand inhabitants are lighted with electricity. One firm alone has supplied over five thousand electric motors for driving various machinery. . . . It is without doubt a good thing that the town should become proprietors of its gasworks. I take it we are nearly all agreed upon that point. The question is, What is the value of the goodwill? Are we not paying too high a price? When gas was first introduced for public lighting in the beginning of this century, speaking from memory it cost above four times what it is being supplied for in Edinburgh at the present time. The incandescent electric lamp has not been in use ten years, yet it can already compete favourably in price with gas in many instances. Who can say that another ten years may not see still further improvements, more especially as the present Government has pledged itself to amend favourably the Electric Lighting Act of 1882? If this were done, and electricity placed on an equal footing with gas, capitalists would come forward, and electric lighting would obtain a fair chance of proving to the public its merits. Ten years is a short period in the life of a town. The gasworks are not likely to run away, nor is it possible for the goodwill thereof greatly to appreciate. I hold, on the other hand, that it is possible and likely that the goodwill will depreciate very considerably, and that, therefore, Edinburgh should wait —I am, &c.,

6, York-place, Edinburgh, 1st November, 1887. W. GEIPEL.

Extracts from Letters addressed to the "Scotsman" against the Purchase of the Edinburgh Gas Works

"October 10th, 1887.

"There is the fact that lighting by electricity is yet merely in its infancy.

"Why, only last winter a project was freely mooted for lighting all the shops in the line of the bridges with electric light."

Signed by D. M. JAMIESON.

"October 11th, 1887.

"Electricity can never supplant gas in the very many purposes to which the latter can be put." Signed by "AGREEMENT."

"October 12th, 1887.

"Indeed, the gas companies themselves throughout Britain now recognise that they can only compete with oil and electricity by steady and persistent reductions in their prices."

Signed by J. S. CLARK.

"October 29th, 1887.

"In my view, having regard to the present state of the keen competition between gas on the one hand and oil and electricity on the other, no more fallacious or futile argument could well be urged." Signed by J. S. CLARK.

Frictional Electricity.

25. Describe and explain the construction and action of the essential parts of Sir W. Thomson's quadrant electrometer.

Answer. Thomson's quadrant electrometer as now made consists of a cylindrical metal box, usually made of brass, completely divided into four quadrants, A, A, B, B, the two quadrants, A, A, being connected by means of a wire, and likewise the two quadrants, B, B. Within this box is a light flat movable conductor, C, of the form shown in the diagram, and usually made of aluminium, suspended so as to be capable of turning about a vertical axis.

The directive force required to give a definite position of equilibrium to the needle, when not acted on by the quadrants, may be obtained, if a single silk fibre is used for the suspension, by attaching a small magnet to the needle, or a bilifar suspension may be used, or the needle may be suspended by a single torsion fibre, such as a glass fibre, for example.

The needle is maintained at a constant high potential by being connected with the interior coating of a Leyden jar. The interior coating of the jar consists of strong sulphuric acid, to keep the air within it dry, and so enable it to retain its charge for a considerable time. The electrical connection between the jar and the needle is usually effected by means of a fine platinum wire depending from the needle, and carrying a platinum weight immersed in the acid, an arrangement which also serves as a damper to steady the vibrations of the needle.

The suspension should be so arranged that in its normal position the axis of the needle may lie in one of the two vertical planes separating the quadrants, as shown in Fig. 24.

If when the needle is charged, two conductors at different potentials be connected with the two pairs of quadrants respectively, the needle will be deflected in such a direction as to oppose more of its surface to the pair of quadrants in connection with the conductor, between which and the needle there is the greater difference of potential. This deflection will be approximately proportional to the difference in potential of the pair of conductors, and the instrument enables us, therefore, to compare the potential differences of two or more pairs of conductors. By earth connecting one pair of quadrants during a series of measurements, we make the earth

Digitized by Google

one of each pair of conductors, and we therefore obtain the relative potentials of the different conductors, assuming the potential of the earth as zero.

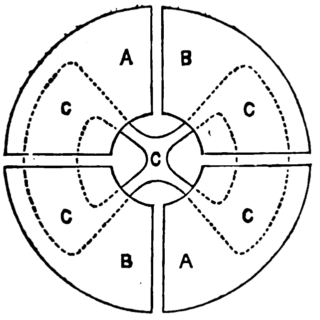

FIG. 24.

26. Two insulated metallic plates are placed facing each other, and each of them is connected with a separate gold leaf electroscope. If one plate is charged, the leaves of both electroscopes diverge. If, now, an unelectrified slab of sulphur is introduced between the plates without touching either, state and explain the effect on each electroscope?

Answer.

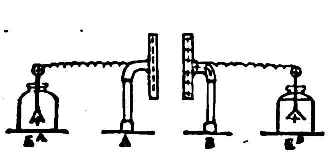

FIG. 25.

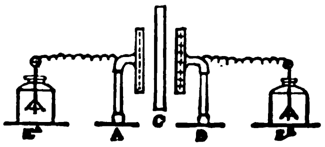

FIG 26.

Let A and B be the two insulated metallic plates connected respectively with the electroscopes E_A and E_B. Let B be charged, say, positively; then the electroscope will share this positive charge, and the electroscope E_A will become positively charged by induction.

When the plate of sulphur C is introduced between the plates A, B, its specific inductive capacity being greater than that of air, the inductive action between A and B will be increased, increasing the negative electrification of the face of A opposite to the sulphur, and therefore also increasing the positive electrification of the electroscope E_A; and again increasing the positive electrification of the face of A opposite to the sulphur, and therefore diminishing the positive charge on the electroscope E_B. The effect of introducing the slab of sulphur will therefore be that the leaves of the electroscope E_A will diverge more, and those of E_B less.

27. A metal ball, A, is placed at a distance of 1ft. from an electrified ball, B. It is then connected for a moment with the earth. If the ball A is now placed 2ft. from B, and again connected with the earth, compare the charges acquired by A in the two cases and explain the results, assuming that in each case the charges of both A and B are uniformly distributed over them.

Answer. If we assume the charges to be uniformly distributed over the spheres, we have, firstly, the potential of A inversely as the distance between the centres of the two spheres A and B; the potential in the second case, when A is 2ft. from B, will therefore be half its value when at a distance of 1ft.

Again, the effect of earth-connecting will be in each case to induce a negative charge on A of such amount as to reduce its potential to zero, the potential of the earth. The charge in the second case will therefore be half that in the first.

28. An electrical machine is placed in an insulated chamber which is lined inside with tinfoil. The rubber of the machine is connected with the tinfoil. What will be the effect upon an electroscope placed outside and connected with the chamber when the machine is in action? Explain your answer.

Answer.—There will be no effect upon the electroscope, for we know from Faraday's ice pail experiments that no interchanges, which may take place between the electrifications of different bodies completely enclosed in a hollow conductor, will produce any change in the external electrification of the conductor, provided that no alteration is made in the total amount of electricity within or upon the conductor. The fact that the electroscope remains unaffected in the case considered shows that when the electrical machine is worked, positive and negative electrifications are produced in equal amounts.

29. How would you arrange an experiment to deflect the needle of a galvanometer by a current produced by a frictional electrical machine? Would it be necessary, in such an experiment, to insulate the wires connecting the galvanometer with the electrical machine more carefully than if a galvanic cell were used in place of the machine. Give reasons for your answer.

Answer. The conductor and rubber of the machine should be connected with the binding screws of a delicate reflecting galvanometer, G, consisting of a very large number of turns of very fine wire, as shown in Fig. 27. On putting the machine in motion, the needle of the galvanometer will be deflected by the current from the machine.

It would not be necessary to be more careful about the insulation when using a frictional machine than if a galvanic cell were used,

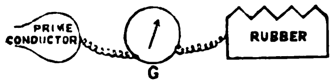

FIG. 27.

because the metallic circuit is complete in each case, and there is therefore no reason why greater care in insulating should be required in the one case than in the other.

The current will always take the path of least resistance, and when the resistance of the circuit in which we wish it to flow is very high, as is the case when the metallic circuit is broken and air or other non-conductors are interposed through which the discharge takes place by sparking, as in most experiments with the frictional machine, it is necessary to have high insulation, so that the desired circuit should still be the one of least resistance.

(To be continued.)

PRIMARY BATTERIES FOR ILLUMINATING PURPOSES.

At a meeting of the Society of Engineers, held in Westminster Town Hall, on Monday, November 7, Prof. Henry Robinson (President) in the chair, the following paper was read by Mr. PERRY F. NURSEY (past President) on "Primary Batteries for Illuminating Purposes":—

INTRODUCTORY.

If there is one branch of practical electricity the pursuit of which is more attractive to the electrician and the inventor than another, it is undoubtedly that of the generation of an electric current for illuminating purposes by means of a primary battery. Proof of this is to be found in the hundreds of patents which have been applied for in this connection during the past few years, and in the many attempts, unsuccessful and otherwise, to produce a commercially practicable primary battery during the same period. The reason for the attractiveness of the subject is to be found in the costliness of the steam-driven dynamo electric system, which, as regards small installations, and with all its excellent progress, still leaves a very wide and remunerative field open for a cheap and efficient primary battery. The prize is great, while the means of winning it would appear to be simple enough when understood. We have only to discover cheap and efficient active and inactive elements, and wed them by means of an equally cheap and efficient depolarising medium, and success is achieved. "Far more easily said than done" will be the thought now naturally passing through the minds of all. It is the author's intention in the present paper to endeavour to ascertain how far we have succeeded in producing such a battery as shall conform to the everyday requirements of ordinary life. In doing this he does not purpose pursuing the subject so much from a scientific as from a practical and an economic point of view. Scientifically speaking, the primary battery for light-producing purposes has long been a practical success. Commercially speaking it is not so yet, except in special cases, and this notwithstanding the great strides it has made during the last five or six years in that direction. In treating his subject, the author proposes first to briefly indicate the principles of the primary battery, and to outline its history, and then to describe in chronological order the various batteries of this class which he has had the opportunity of inspecting from time to time as they were introduced to public notice by their respective inventors.

After having dealt briefly with the history of the subject the author proceeded to the

CONDITIONS REQUIRED IN BATTERIES FOR GENERAL LIGHTING.

Any battery to be of use for practical electric lighting on a broad and general scale must fulfil, amongst others, the following leading conditions:—

1. It must be capable of producing a constant current.
2. It must possess a fairly high and constant electromotive force and a small and constant internal resistance.
3. The elements and the exciter should be of a simple, innocuous, and inexpensive character, and should not give out noxious or even unpleasant fumes.
4. There should be no waste going on while the battery is not doing work.

Digitized by Google

5. It should be capable of being cleansed and replenished easily and without any kind of personal danger from any source.

6. It should be of small dimensions, and capable of being managed by the most ordinary capacity.

The Holmes and Burke Battery.

The first primary battery that came under the author's notice was that of Messrs. Holmes and Burke, which was brought out in November, 1883, and constituted then a new departure in the practice of electric lighting. All the information the author could at that time obtain respecting it was that the elements were carbon and zinc, and that the essence of the invention consisted in the mechanical arrangement of the battery and the nature of the exciter. The author saw a large room lighted by a number of Swan glow lamps of five candle-power each, which derived their current from batteries placed in an adjoining room. It was stated that a sixteen-cell battery was equal to the supply of eighteen glow lamps of five candle-power each. With regard to cost, it was stated that the light was maintained for twenty-four hours, at an average rate of one-eighth of a penny per light per hour, *i.e.*, one penny per eight hours' continuous light; but that the expense varied with the size of the lamps and the amount of electricity used. As no particulars were given of the construction or equipment of the Holmes and Burke battery, no opinion of its practical or commercial merits can be formed. It is worthy of note, however, that Messrs. Holmes and Burke were, so far as the author is aware, the first to contest the field open for primary batteries for general lighting purposes. Installations of this system have been fitted up in several houses, including that one of our members, Mr. A. F. Yarrow, who recently informed the author that the battery had worked very satisfactorily during the three years it had been in use.

The Holmes and Burke battery has lately been improved by Mr. W. Webster, jun., managing director of the Railway and Domestic Electric Lighting Company, and Mr. Octavius March, their electrician, who have afforded the author the following particulars of the improvements. The best known depolariser is no doubt nitric acid, but the difficulty of using it in a battery constantly in use has long been recognised. The depolarising fluid in the new Holmes and Burke battery is one in which the advantages of nitric acid are obtained without the disadvantages. This is done by using the materials from which nitric acid is made, in such a way that the nitric acid required for depolarisation is generated in the battery by the electro-chemical action. This generation ceases when the battery is at rest, and consequently there is never any free nitric acid present in the cell. The battery is a double fluid one, using a special depolarising fluid with carbon plates in a porous cell, and having zinc plates in the outer cell with dilute sulphuric acid. The working E.M.F. of the battery in open circuit is 1·8 volt. The fall of potential during discharge is almost nothing. The internal resistance of the sized cell generally used is 0·03 ohm. Consequently a discharge of 10 amperes can be obtained at an E.M.F. of 1·5 volt. The principal constituents of the fluid are nitrate of soda, the cheapest salt obtainable (except sodium chloride), and sulphuric acid, the cheapest acid. The cells are usually arranged in sets of eight, and provision is made for filling and emptying eight cells simultaneously.

Great difficulty is usually experienced in preventing the various connections and contacts from corroding. Mr. March finds the best method is to dispense with all binding screws, and to obtain the necessary contacts by means of mercury cups of a special form. In the latest form of battery the company have also been able to dispense with wooden tops or covers, the necessary recesses for the mercury connections being formed in the stoneware of which the cell is made. The plan now adopted also adds materially to ease of manipulation, as a zinc plate can be taken out for inspection and amalgamation at any time without breaking the main circuit.

The cost of material for maintenance may be taken to be as follows:—Sixteen cells will maintain ten 10 candle-power Swan lamps for about twenty hours. The cells usually hold about three pints of fluid per porous pot, or six gallons for the sixteen; this at 9d. per gallon = 4s. 6d.; acid for outer solution, about one gallon, 1s. 6d. = 6s. The work done would be about five electrical horse-power hours, and the zinc consumed (about 2lb. per electrical horse-power hour) would amount to 10lb. at 3d. = 2s. 6d., bringing the total up to 8s. 6d. This gives 200 lamp hours for 8s. 6d. = 0·5d. per lamp hour. The cost of a gas burner giving about the same light with gas at 3s. 6d. per 1,000 would be ·21d. It is only right to add that these conditions can only be obtained where a battery is properly attended to. Great waste naturally takes place where there is neglect. The time requisite for attending properly to a sixteen-cell battery should not exceed ¼ to ½ an hour daily for examination, and one hour for charging and amalgamating once or twice a week according to the amount of current used. By the courtesy of the Railway and Domestic Electric Lighting Company a set of eight cells, composing a Holmes and Burke battery driving twelve Swan 5 candle-power glow lamps is here in illustration of the system.

The Ross Battery.

The next example of this class of generators came under the author's notice in December, 1883. This was the primary battery of Mr. O. C. D. Ross, in which the special merits claimed were economy and constancy. In this battery zinc plates were used, and the liquid electrolytes were stated to be of an inexpensive character, and the consumption of zinc so small that it only represented a cost of 2d. per hour for the electrical unit. By a simple arrangement the cells could all be simultaneously charged with the liquid exciter, and subsequently discharged by merely raising or lowering a framework of tubes, and turning on and off a tap. The zinc which was consumed in the battery was recovered in a solid form and in augmented quantity as oxychloride of zinc. This product, it was stated, formed the principal ingredient of a new insulating material for covering electric conductors. It was found that with a single charge of the chemical liquid a substantially constant current could be obtained for upwards of twelve consecutive hours. That point was verified by the report of a professional tester, who carried out a series of experiments with a few cells forming a portion of this battery. Upon the occasion of the demonstration, at which the author was present, a Swan glow lamp, stated to be of 100 candle-power, was first shown, after which thirty-nine Swan lamps of 10 and 7 candle-power were lighted. Twenty Woodhouse and Rawson glow lamps, each of 20 candle-power, were subsequently shown, and during the time they were running the current was switched on to a motor which drove a 16in. Blackman ventilating fan, with but slight detriment to the light of the twenty glow lamps. A powerful arc lamp was also brought into action, all the other sources of consumption of current being of course switched off. In all cases the light was of good quality and very steady, and in these respects the demonstration was very satisfactory. The arrangement for charging and discharging the cells was very good, but the battery was very large in proportion to power, and emitted a decidedly objectionable smell. The nearest approach to an estimate of the cost of the light produced was that it was slightly more expensive than gas. As the battery was working in the City of London the price of gas may be put down at 3s. per thousand. Mr. Ross recently informed the author that his battery had been successfully applied to the lighting of a house in Queen's-gate for two years. Mr. Ross, however, does not now attach any importance to the recovery of the oxychloride of zinc as a by-product, for the reason that in house lighting the quantity would be too small to make it worth collection. Mr. Ross informs the author that quite recently he has made a discovery in connection with the action of the separate cells of his battery which will greatly simplify the daily manipulation of discharging the spent solution and replenishing the cells with fresh.

The Coad Battery.

In January, 1884, the author inspected the working of the Coad primary battery, which had been publicly exhibited previously, and had then recently undergone several modifications and improvements. No particulars were given as to its construction beyond the statement that the battery had a specially prepared zinc immersed in a special liquid exciter, one feature being that the zinc was not removed from the bath during non-use, there being, it was said, no waste. The battery appeared to be of small size for its power, inasmuch as two batteries of ten cells each were contained in a case 3ft. high by 2ft. wide and 20in. deep. Each 10-cell battery was said to be equal to the supply of one Swan glow lamp of 20 candle-power, and it was stated that the battery would give a full light for forty hours, after which it had to be recharged with the liquid. The cost of maintaining a battery of ten cells for forty hours was put at 1s. 3d., and each cell was said to yield a large quantity of chrome. The glow lamps gave an excellent light, and so far as it went the demonstration was very satisfactory. The author, however, has not heard of this battery since the date given, and his recent attempts to trace it have proved futile

The Lalande Battery.

About the middle of 1884 a considerable amount of attention was being directed to the Lalande-Chaperon primary battery, by means of which it was claimed that a current of electricity could be generated and used either for lighting or for driving machinery, and that certain of the elements which produced the current became converted during the time they were doing their work into a substance of greater value than they possessed before the battery was started. The battery was somewhat large, that which the author inspected being composed of forty-eight cells, each 1ft. cube. It was stated that the battery was capable of maintaining fifteen glow lamps of 10 candle-power each, or of driving a small motor. Each cell of this battery consisted of an iron tray, on the bottom of which was placed the depolarising agent, which was oxide of copper. Just above this and supported at each corner was a plate of zinc, the cell being filled with a solution of caustic soda. Under ordinary circumstances, and when the circuit was open, no action took place between these elements; but on the circuit being completed the work of decomposition commenced. The oxygen of the oxide of copper combined with the zinc and formed oxide of zinc, metallic copper being left behind. When the battery was exhausted the zinc was recovered from the liquor in the form of an oxide, and this was stated to be 56¼ per cent. more valuable than the metallic zinc, and was to be used for making paint and for other industrial purposes. This remarkable increase in value was said to be obtained by reason of the metal having gained 25 per cent. in weight by its absorption of oxygen, and the oxide being also 25 per cent. more valuable than the metal, weight for weight, thus giving a total increase in value of 56¼ per cent. as stated. The oxide of copper was to be revivified and used over and over again. The claims mainly advanced for this battery were, that it was absolutely constant so long as the elements in it were kept in a state of efficiency; that the action upon the zinc was very gradual, that while the light was not being used there was no waste going on, and that no noxious smell was given off, as is the case when acids are used. This latter point was clearly demonstrated upon the occasion of the author's inspection, as was also the ability of the battery to give an excellent and steady light. A series of nine Woodhouse and Rawson glow lamps, each of 10 candle-power, were used in circuit. An Ayrton and Perry's motor was driven by the current, and showed the battery to be capable of doing good work in that respect. The cost of the light produced was stated to be much less than that of gas.

Although the battery is the invention of M. Lalande, the credit of attempting to utilise the residual product from it is due to Mr. J. Berger Spence, head of the firm of manufacturing chemists bearing that name. And it came about in the following manner:—The manufacture of oxide

Digitized by Google

of zinc is in ordinary a costly process, and Mr. Spence had for some time past been casting about for a more economical method. Amongst other things, he tried electrical decomposition; and, whilst engaged in his experiments in that direction, he became acquainted with M. Lalande, who, he found, had a battery which was giving exactly the result Mr. Spence wanted. The introduction of the battery for lighting purposes, however, is due to Mr. Hugh A. Fergusson, under whose hand it has been considerably modified and improved since the author saw it in June, 1884.

In the improved battery the elements consist of zinc, caustic potash, and oxide of copper. The cell consists of a cast-iron trough, 24in. long, 12in. wide, and 18in. deep, holding about 15 gallons of liquid. The negative plate (positive pole) consists of folded iron gauze, into which is pressed an agglomerate mixture of oxide of copper, in a granular form (copper scales), and chloride of calcined magnesia in certain proportions. This, when heated, forms a hard porous plate. The oxide of copper acts as a depolariser, and is the essential feature of the battery. When the battery is worked out the copper is left in metallic form, and by heating the plates in a furnace it is reoxidised, and again ready for use. The size of the plates is 20in. long by 18in. deep, and ⅜in. thick. There are four in each cell, presenting a working surface in liquid of about 1,280 square inches. Each plate contains about 10lb. of copper, or 40lb. per cell.

The positive plate (negative pole) consists of a zinc plate, of which there are two in each cell, the dimensions of each being 20in. by 15½in. by ¼in., and weighing 20lb. or 40lb. the two in each cell. The working surface is about 1,240 square inches. The exciting liquid consists of a solution of caustic potash at a specific gravity of between 1·25 and 1·3. The electromotive force through high resistance is stated to be slightly under one volt. In the earlier experiments the lamps were run direct from the battery, and although this answered very well in many cases, there were found to be objections to this method. The battery is therefore now worked in combination with another battery of secondary cells or accumulators, which are charged in parallel from a set of six primary cells in series. This system of charging accumulators in parallel is found to answer very well, as the cells are more evenly charged than in the series system. The secondary cells are connected to a switch for turning them into series and on to lamp circuit, or in parallel and on to battery circuit. By this means not only are the objections connected with running a lamp circuit direct from primary cells avoided, but there are said to be collateral advantages of great importance in connection with the system.

Several installations of the Lalande system have been fitted up in London and elsewhere, and are reported to have given every satisfaction. In practice the cells are placed in a cellar, from which there is an opening to the street sufficiently large to pass the plates and primary cells through. When the solution had become saturated with zinc, it was formerly removed by means of a tank cart, in which the exhausted solution was put. In the future, however, a vacuum cart is to be used in order to save time. By this means a battery of six cells, holding 90 gallons, will be emptied in 10 minutes. The company working the invention will maintain the batteries, and the carts will visit the houses where they are in use at stated periods to re-charge them whenever it is necessary. The specific gravity of the solution in the primary cells acts as a reliable indicator of this. The solution is to be taken to the works, where it will be treated in two ways. First, by the process invented by Dr. Squire, by which the zinc is obtained back in the form of sulphide of zinc, and is sold for paint purposes; and, secondly, by the process invented by M. de Lalande, by which, it is said, the zinc is obtained back in a greater state of purity than when it was originally put into the battery. The caustic solution will also be returned to its original condition, and the oxide of copper gauzes will be re-oxidised for further use. This latter process has only been completed within the last few months, and by its means it is claimed that electricity can be supplied at a lower cost than has yet been supposed possible. The Lalande system, as a whole, has been examined by several scientific men, and the reports that have been made by them are very satisfactory. The reporters, as regards the electrical part of the system, were Prof. Tait and Prof. Crum Brown, of Edinburgh, and Principal Jamieson, of Glasgow. The chemical part has been examined by Prof. Dittmar, of Glasgow.

The Lalande system is illustrated by a battery of six cells, with lamps running, which Mr. Fergusson has kindly placed at the author's disposal upon the present occasion.

The Skrivanow Battery.

The attempt which was made in the early part of 1885 to destroy the Houses of Parliament by dynamite led to the introduction to public notice of a new search light driven by a primary battery, and designed for use in small boats on rivers. It was introduced by Mr. Isidore Spielmann, who about the time stated experimented with the apparatus, which was in the first instance intended for the use of the river police in patrolling the Thames opposite the Houses of Parliament. The object was to throw a strong light from the middle of the river on to the Palace of Westminster. The difficulty to overcome was the obvious one presented by the size of the police boats, which does not admit of their being fitted with engines, dynamos, or bulky accumulators. The only source left was that of the primary battery, and from this was derived the light with which the trials were made. The battery used was the invention of Mr. George de Skrivanow, a Russian inventor, who died about that time. The elements of this battery consist of a small packet of chloride of silver and two plates of zinc placed in each cell with a weak solution of caustic potash. In applying this battery to domestic lighting, a small one is placed in the stand of a moderator or other similar kind of lamp, which can thus be utilised for the purpose, a glow lamp being fixed on the top in place of the ordinary burner. The author inspected a number of lamps thus arranged. Taking one as typical of the rest, he may explain that it had a battery consisting of three boxes, each measuring only 4in. by 2in. by 1in., and which supplied the current to a glow lamp of Italian manufacture, the light being an exceedingly good one. It was stated that it would burn for twelve hours with undiminished brilliancy, but that at the end of that time the silver would be converted into pure silver, and would require to be revivified. This is effected by washing it in a solution of nitric and hydrochloric acid. It is then replaced in the battery for further use, there being no waste of the silver. The marked advantages of this system of domestic electric lighting, beyond the portability of the lamps, are the absence of fumes, the small battery capacity, and the great electromotive force, this being 1½ volt for each cell, which is only 1in. in width. Applied to the arc system, the Skrivanow battery showed its power, a light of 250 candles being produced from a couple of batteries measuring 10in. long by 8in. wide and 6in. high. This installation, which the author also inspected, was, in fact, the one already referred to as having been used as a search light on the Thames by the police.

The Skrivanow battery was also applied to a miner's lamp, and an example was brought under the author's notice in January, 1886. This lamp consisted of a metal casing 7in. high by 3½in. wide and 3in. deep from front to back, and which contained the battery. Projecting from the front of the case was a 3-candle glow lamp of German make, and which was properly protected, and had a reflector. The battery was composed of three cells, each 6in. by 3in. by 1in., and produced an excellent light of 3 candle-power, which, it was stated, would last nine hours. The current given off by this battery was in excess of the requirements of the miner; but there were smaller lamps, notably one of circular form 3in. in diameter and 3in. deep, and of 2 candle-power, burning for five hours. Another, of the quadrangular type, was 6in. high, and of 3 candle-power, but only burning for seven hours and a-half. The cells were hermetically sealed, so there was no fear of escape of the liquid portion of the contents, and the lamp could be inclined at any angle without fear of extinction.

(To be continued.)

PROF. SILVANUS P. THOMPSON ON TECHNICAL EDUCATION.

A conference on technical instruction was held at the City and Guilds Technical College, Finsbury, on Saturday evening last, under the presidency of Mr. J. Rowlands, M.P. Prof. Silvanus Thompson, Principal of the College, read a paper upon "The Present Position of the Technical Instruction Question." He began by giving a brief outline of the efforts that have been made during the past decade to supply technical education by the development of real technical schools in many of the principal provincial towns, and by the establishment of technical, or at least of technological classes, out of the old "mechanics' institutes." Simultaneously with these there had grown up what are known as university colleges, which, he said, were of a more purely scientific character, and which afforded the means of acquiring real technical education, more particularly in those cases where schools of engineering had been developed. The problem of technical instruction could not, however, be solved by the establishment of a dozen science colleges. They met the wants of a very small portion of the population. For the vast majority, for those who must be apprenticed to a craft, they did nothing, at any rate directly, save in those cases where by the holding of evening classes they met the wants of those who discovered—often, alas, too late—how little their previous education had fitted them for their career in life. The lecturer then proceeded to sketch the difference in the grade of instruction imparted at the numerous institutions in the metropolis wherein educational work of a technical character is going on, and gave an exhaustive history of the Finsbury Technical College, its objects, and the methods of instruction therein adopted. Briefly stated, he said that three points might be emphasised:—Firstly, all the instructors of the Finsbury Technical College are men who have learned their work from the industrial side, and who can therefore show how theory can be applied to practice; they are trained workers endeavouring to teach the principles of their craft, not schoolmasters trying to teach trades. Secondly, the main work of the college is conducted, not in the lecture room or class room, but in the laboratories, workshops, drawing office, and studios. Thirdly, there is no cramming for examinations, therefore none of the baneful effects of striving after payment by results; no inducement to superficialism or dilettanteism; in a word, students and instructors alike come to the college not for amusement but for work. Prof. Thompson next went on to comment upon the great strides that have been made in recent years on the Continent with regard to the subject of technical instruction, making special reference to the Technical High School of Berlin, the cost of which, he said, including its magnificent collection of apparatus, casts, models and instruments, was about £690,000, the annual grant to which on the part of the municipality being £37,380. It had a staff of 58 professors besides 43 assistants. The main subjects of instruction taught were architecture, building, engineering, chemistry, photography, metallurgy, physics, and electrical engineering. The expenditure for its maintenance was made up as follows:—Salaries of 58 professors and 43 assistants and instructors, £16,000; apparatus and materials, £3,000; maintenance of building, £1,050; office expenses and postage, £6,190; heating and ventilation, &c., £3,000; library, £730. He was far from saying that the City of London ought to copy the City of Berlin. Much less would he propose, on the ground that London was four times the size of Berlin, to erect a building four times as great. On the contrary, he maintained that as Englishmen their business was to develop their own system to meet their own needs. Only let them keep their eyes open to the magnitude of the efforts made to wrest from them their industrial supremacy by providing such ample means of acquiring technical

Digitized by Google

instruction. He next proceeded to examine the wide question of apprenticeship, of which he said there were only two recognised kinds in this country. In one, the apprentice, entering at about 14 years of age, served seven years as a workman, receiving practically nothing for his work beyond instruction in his trade, save a small pittance for his weekly maintenance. In the other the young man was received into the works at the age of eighteen or nineteen as a premium pupil, to serve an apprenticeship of a very different and often very unsatisfactory kind. But now it would seem there was a third sort of apprenticeship in which the technical college or school played a part—the work of the technical school or college being either preparatory or supplementary to the commercial apprenticeship in the shops. The aim of the Finsbury College differed from other institutions of the same class in this, that its two years' course was designed to obviate the payment of a premium, and to enable the student, when at about the age of seventeen he entered the works, to take his place there as a working apprentice, the same as if he had been already apprenticed there for three years. In other words, it was an attempt to create a modified apprenticeship, lasting not more than five years, wherein the college course took the first two and the shops the last three. The success of the system had already passed the expectation. Another most important question arising out of the consideration of the present position of technical instruction was the form to be given to its future organisation, and to complete anything like a national organisation the following additional departments to the Education Department would require to be organised :—A Department of Secondary Education, including under its operations three classes of schools or colleges, namely—(1) Higher literary or grammar schools ; (2) Technical schools and colleges ; (3) Schools of commerce. A Department of Higher Education, including under its supervision—(1) Normal schools for training teachers ; (2) University colleges of the modern type ; (3) the several universities of Great Britain. The organisation of secondary education was a matter of absolutely vital importance in this country, but one of which, in the clamour of party politics, scarcely a syllable was heard. What was the best form to give to the national organisation of technical instruction ? At present there appeared to be three claimants to the honour of directing it in the future—(1) the City and Guilds of London Institute, (2) the National Society for the Promotion of Technical Education, and (3) the Department of Science and Art at South Kensington, the characteristics of each of which he fully set forth, pointing out with regard to the latter that the very objects at which it aimed were defeated by the stereotyped methods and ideas of the official mind that governed it, which had the tendency to divorce the artist from the workman, which was the very thing that true technical education deplored and sought to remedy. In conclusion Prof. Thompson said :—"What, then, must be done for the national organisation of technical instruction ? In the writer's opinion the first and most important point of all is to secure the creation of a real Education Department under a real Minister of Education. At present we have no Minister of Education, only a Vice-President of Council, whose duties appear to be extensive and peculiar. They comprise apparently the work of looking after the regulations for statute fairs and diseases of cattle, of supervising the Elementary Education Department and the Science and Art Department, and of superintending the proceedings of the Judicial Committee of the Privy Council. What is wanted is a real Minister of Education, presiding over an organisation in which the Elementary Education Department, the Science and Art Department, and the Departments of Secondary (including Technical) and Higher Education, should all take their appropriate places under officials responsible directly to the Minister himself, and not to that mysterious body "My Lords of Council.' No attempt by Parliament to organise technical instruction can be satisfactory unless it involves the appointment of a responsible Minister of Education, and a reconstruction of the whole departmental machinery."

A brief discussion followed, in which several working men took part, the general consensus of opinion being that technical education, as represented by Prof. Thompson, would eventually tend, by the superior workmanship that it would call forth (thereby defeating foreign competition), to benefit not only the workman but the public at large.

Votes of thanks were afterwards passed to Prof. Thompson and the Chairman, and the proceedings terminated.

LEGAL INTELLIGENCE.

Smart, Block and Co. v. United Telephone Company (Limited).

This action was on Monday last heard before Mr. Justice Mathew and a special jury.

The plaintiffs, who carry on business in London-wall as importers of Swiss embroidery, &c., claimed to recover damages for injury caused to their goods, as they allege, through the falling of a telephone wire belonging to the defendants during the great snowstorm which took place at the end of December, 1886. The wire in question was stretched over the roof of the plaintiff's premises, and the allegation was that in its fall it knocked away a gutter, and in consequence the water from the melting snow entered the warehouse.

The defence was that the weight of the snow caused the gutter to fall, and that the wire had nothing to do with it.

Mr. Crump, Q.C., and Mr. Morten appeared for the plaintiffs ; and Mr. Moulton, Q C., and Mr. Daniels for the defendants.

The Jury returned a verdict for the plaintiffs, damages £300, an agreed amount.

Judgment accordingly.

COMPANIES' MEETINGS & REPORTS.

The "Pilsen," "Joel," and General Electric Light Company (Limited).

The sixth ordinary general meeting of the shareholders of the above Company was held at the Cannon-street Hotel on Thursday, the 10th inst., under the presidency of Sir Rawson W. Rawson, K.C.M.G., C.B.

The SECRETARY (Mr. W. H. Trentham) read the notice convening the meeting, and the Directors' report and statement of accounts were taken as read.

The CHAIRMAN: Gentlemen, I shall not detain you by many observations. Our object to day is mainly to sanction the dividend which the Board are able to propose to you. That dividend is but a small one. We had hoped that it might have been at least equal to that of the preceding year, but the circumstances of last year have not been favourable for electric lighting generally either with ourselves or with other companies. Our object, as you know, from the beginning has been to carry on our business with the capital that was left to us without calling upon our shareholders to increase it. Our capital, as is shown in the report, is but a very small one—not exceeding £7,000—and we have been desirous of entering upon no speculative business, of uncertain return, which should diminish that small capital. We see, like other companies, a future for electric lighting, but until some Bill passes the Legislature there can be no large development of the distribution of electricity for lighting purposes. At the present time it seems rather that people are desirous of receiving electricity as they do gas, and that the prospect of profitable investment of our capital is in the way of installations. We have therefore, since our last meeting, formed a new installation at the head of Tottenham Court-road, which, we feel assured, will be a profitable investment and will increase in profit. We have removed our offices from the small building and factory in which they were placed to other premises in Stanhope-street, where there are the means of developing our business to a very considerable and safe extent. We have already had a profitable return for our investment there, and have the prospect amongst the surrounding tradesmen of increasing our profit from that installation considerably. It is very satisfactory that Mr. Baker, who was our original customer in Holborn, has shown that he was so far satisfied with his installation there that he has extended it to another of his establishments. In the same way at Holborn we have increased our means of obtaining customers there by putting in a more powerful engine, which will enable us to run our circuit into Fleet-street and elsewhere, and there we find another proof of the satisfaction that we are now able to give to our customers, inasmuch as Mr. Baker has again entered into a contract to extend the lighting to his establishment in Fleet-street. In the same way other large customers in Tottenham Court-road and Fleet street have contracted to light their establishments. We therefore see for the future the probability—I may say the certainty—of increasing considerably our annual profits, and being able to distribute a larger dividend in future years. But, at the same time, as has been already remarked, our capital is very small, and, as you know, in order to obtain an annual profit from our installations, we must invest a considerable amount of money in the installations themselves, and we therefore feel ourselves at present limited in our operations by the amount of our capital. Your attention has been called in the report to that point and to another in our affairs, namely, the shares that have been forfeited. I do not know that I have anything else to call your attention to, but I may wind up by expressing our feeling of confidence with regard to the safe and profitable working of the Company with its present small capital; and if electric lighting shall become more popular, and there shall be evidence of a desire on the part of persons to avail themselves of it, and we can see our way to a profitable extension of our business, it will be our duty to avail ourselves of every means now at our disposal to extend our business safely, and if those means are not sufficient to call your attention at the next meeting to the circumstances, and to invite your opinion as to the advisability of taking some steps to increase our scope of obtaining a larger profit for our shareholders. He concluded by moving the adoption of the report and accounts.

Mr. HORACE W. SCRIVEN seconded the motion.

Mr. ROSS asked what was the cost of the installation at Tottenham Court-road.

The CHAIRMAN replied that it was about £1,200.

A SHAREHOLDER asked whether the money invested in Consols was available for such purposes?

The CHAIRMAN: Certainly. You can quite understand that it is very much more satisfactory to us to profitably use our money in Consols than to leave it invested at 3 per cent., and therefore you may count on our using these funds as far as we safely can. We must of course always have a certain reserve to meet the opportunity of entering upon some larger enterprise. In further answer to a shareholder he added:—Last year the sum invested in Consols on the 30th of June was £3,500, and on the 30th June, 1887, it was £2,986—a diminution of a little over £500. That amount has been diminished since, and the cost of the engine at Holborn will have to be met out of the Consols.

Mr. SCRIVEN said that they might regard the Consols as working capital.

The resolution was then put to the meeting, and carried unanimously.

The CHAIRMAN next moved, and Mr. ROSS seconded, "That a dividend on the present paid-up capital of the Company, at the rate of 4d. per share on the partly paid-up shares, and at the equivalent rate of 7d. per share in respect of the 100 fully paid-up shares, be sanctioned."

The resolution was carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. SCRIVEN, the retiring Director, Mr. George Lovinge Whateley, was re-elected to his seat at the Board.

Messrs. Brown, Hays and Akers were subsequently reappointed auditors to the Company, and a vote of thanks having been passed to the Chairman and Directors, the proceedings terminated.

The Imperial Continental Gas Association and their Electric Lighting Plant.

The half-yearly ordinary general meeting of the proprietors of this Association was held at the City Terminus Hotel, Cannon-street, on Tuesday afternoon, Sir Julian Goldsmid, Bart., M.P., in the chair.

The following is the only portion of the proceedings which will be of interest to our readers:—

In the course of his remarks the CHAIRMAN said: You have been informed at previous meetings that we were going to light the Opera and the Burg Theatre at Vienna by the electric light. When we undertook to go into that matter we did not do so with the idea of making a big profit, but simply to satisfy the local and imperial authorities. Although there may be many imperfections in what has been done, yet I trust, after the whole undertaking is completed, the installation will work satisfactorily. We are not the first and only gas company that has found it necessary to enter upon electric lighting. It is not so good a thing as gas lighting, and our main reliance must be upon our original specific business—that of supplying good gas light at the cheapest possible price.

Mr. GEORGE LIVESEY: I think, Mr. Chairman, your remarks about the electric lighting of Vienna require a little explanation to satisfy the shareholders that it is right. Of course, I do not pretend to understand much about the working of foreign gas companies. If it were an English company I should speak very decidedly, positively, and emphatically against any gas company in the United Kingdom undertaking electric lighting. Whether your circumstances are different it is not for me to say. I have no doubt that you have acted with great discretion in the matter. I read an account from *The Times* correspondent, some months ago, on the success of this electric installation at Vienna. It said something to the effect that the engineer of the gas company had had great difficulties to contend against, but had succeeded in overcoming them, and I gathered from this report that the engineer of the Imperial Continental Gas Association of London had given the greatest possible help to electric lighting—our great rival. Well, I will not say rival, for I do not believe it is such; but, at all events, by the great skill which this Company's engineer brought to bear upon the matter he had overcome obstacles and difficulties that had puzzled the electricians. I thought that was a very strange thing—that a gas company should undertake to do for electricity what it could not do for itself. Also, I thought that this electric lighting was not productive of profit, and it looked to me as if there was a danger of the profits earned by the legitimate undertaking of the Company being used to bolster up the electric lighting. Further, it occurred to me, why could not the Company have left this electric lighting alone? If the Emperor was determined to have the electric light, by all means let him have it, but do not let the Company be dragged into supplying it. You have stated that you do not expect to make any profit out of the electric light; then what on earth was the use of going in for it at all, unless, indeed, there was something connected with the concession of the Company and the Emperor that rendered it expedient to do so? You have said that we were not the only gas company that had gone in for the electric light. I read of one lately in Italy that bought up the electric company's shares in order to control its working. I think that was another great mistake. Why cannot gas companies leave the electric light companies alone—leave them to do their best or their worst, or fight them legitimately? In England there is no chance of gas companies going in for this electric lighting. Some time ago an English company attempted to get powers

Digitized by Google

to supply electric light, but the Board of Trade opposed the Bill in Parliament; they refused to grant the necessary powers, and the result was that no further attempt was made. My opinion is that gas companies will be able to hold their own, and hold their own against all competitors.

The CHAIRMAN: As far as I am concerned, I have at previous meetings told the shareholders that I am not in favour of going into anything that will not give us a good return for our money. There were special reasons at Vienna that made it desirable for us to accede to the wishes of the imperial and local authorities—not, indeed, with the view of profit, but to keep the position we already occupied. If we can show our competitors what the cost of an electric station is, and what return it is likely to give, they will not be so likely to enter the field as otherwise they would be. That is a result not to be overlooked. With a good many years' experience of this Company, I am strongly of opinion that it was desirable, under the circumstances, to undertake this work. Of course, the business of the Company cannot be measured by the position and method of management of companies in England under statutory powers, and which exist for ever and ever. In the case of foreign companies, you have affairs to arrange and settle with municipal and other authorities that never occur to English gas managers.

The report was then put and carried unanimously.

West India and Panama Telegraph Company.

Report of the Directors to be presented at the twenty-first ordinary general meeting, to be held at Winchester House, 50, Old Broad-street, E.C., on Wednesday, the 16th inst., at 12 o'clock:—

The amount to credit of revenue is £47,003. 7s. 4d., and the expenses have been £25,543. 4s. 4d., leaving a balance of £21,460. 3s., which, with the balance of £1,919. 15s. 6d. brought from last account, makes a total of £23,379. 18s. 6d. Of this sum the Directors have placed £6,000 to reserve, leaving an available balance of £17,379. 18s. 6d., with which it is proposed to deal as follows:—

Payment of 9s. per share on account of arrears of dividend on the First Preference shares	£15,553	7	0
Balance to current half-year's account.............	1,826	11	6
	£17,379	18	6

The traffic receipts for the six months show an increase of £1,792. 2s. 7d., as compared with the corresponding period. The Company's ss. "Grappler" came to London in June last, and, after being docked and overhauled, returned to the West Indies with 250 knots of deep-sea cable for repairing purposes. She has since repaired the original Jamaica-Po to-Rico section, which was interrupted on the 28th November, 1885. With the completion of this repair the duplication of the most important section of the Company's line is restored. The shareholders were informed in the last Report that the Directors had addressed communications to the French Government, pointing out the inevitably disastrous financial results of the proposal which had been submitted to the French Chamber of Deputies, to authorise the guarantee of a gross revenue of £40,000 per annum for the construction of a cable between Para (Brazils) and New York, touching, among other places, at the French islands of Martinique and Guadeloupe, already served by the system of this Company. The directors have now to report that, notwithstanding persistent efforts in favour of the scheme, the evidence of its unremunerative and unnecessary character was so overwhelming that the French Chambers decided not to proceed with it. With the experience of this Company of the insufficiency of West India traffic to support a remunerative telegraphic system, it is surprising to find attempts made to compete for a portion of a business, the whole of which does not yield a dividend on the larger part of the capital employed. Any proposal for the establishment, on commercial grounds, of a competitive line, if put forward with a view to any profit to those who might be induced by promoters' representations to find the necessary capital, has only to be impartially examined to be rejected. The whole of the £50,000 debentures which fell due on the 31st December last has now been extended for a further term of five years at 5 per cent. per annum, instead of 6 per cent.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended Nov. 4th amounted to £3,492.

EASTERN TELEGRAPH COMPANY.—This company notifies that it has opened for traffic a new cable between Porthcurnow in Cornwall and Gibraltar, Malta, and Zante, thus putting Greece and Turkey in direct cable communication with this country. The rate to Greece is the same as by the existing land routes, viz., 7½d. per word. To Turkey the rate is 10d. per word.—The same company also notifies the opening of a new telegraph station at 37, Holborn-viaduct, where telegrams will be accepted for transmission to all parts of its system.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY.—This company gives notice that on Wednesday, 16th inst., at 2 p.m., at the company's offices, Winchester House, 50, Old Broad-street, 257 First Mortgage Debentures of £100 each will be drawn for payment on 2nd January, 1888. Notice will be given by advertisement of the numbers of the debentures drawn.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this company for October amounted to £23,160. From 1st January to 31st October, 1887, they amounted to £220,880; for the corresponding months of 1886 and 1885 to £217,800 and £241,640 respectively.

OPPERMANN ELECTRIC LIGHTING AND MANUFACTURING COMPANY (LIMITED).—The prospectus of the Oppermann Electric Lighting and Manufacturing Company (Limited) has been issued. Capital, £20,000, of which a first issue will be made of 1,000 shares of £5 each. The company is formed for the purpose of taking over the business of electrical engineers now carried on by M. Carl T. J. Oppermann under the name of Lawrence Oppermann, at Crown Works, Amhurst road, Hackney. The works will, however, be removed to Blockley, Worcestershire, where water power is available. The following agreements have been entered into:—(*a*) An agreement, dated the 14th day of October, 1887, between Carl Tunstill John Oppermann of the one part, and Lord Edward Spencer Churchill, on behalf the company, of the other part; being an agreement for the purchase of the business, as stated in the prospectus, for the sum of £1,200, and for securing the services of Mr. C. T. J. Oppermann as manager. (*b*) An agreement, dated the 22nd day of October, 1887, between Hugh Nigel Warburton, of the one part, and Lord Edward Spencer Churchill, on behalf of the company, of the other part. (*c*) An agreement, dated the 22nd day of October, 1887, between Charles Barter of the one part, and Lord Edward Spencer Churchill, on behalf of the company, of the other part. Directors: Lord Edward Spencer Churchill (chairman), Alexander Wm. Hall, Esq., M.P.; Rev. Henry Barter, H. N. Warburton, Esq., C. Barter, Esq., C. T. J. Oppermann, Esq. The last three will join the board after allotment.

SOUTH AFRICAN GAS COMPANY (LIMITED).—This company has been registered with a capital of £100,000 in £5 shares. The objects of the company are to manufacture and supply gas and light in Woodstock and elsewhere in Cape Colony; to carry on at Woodstock the business of an electric light company in all branches, and to carry on the business of electricians, mechanical engineers, and suppliers of electricity for light, heat, motive power, or otherwise.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended 31st October amounted to £3,700.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 4th, were £2,580, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

REMOVAL.—Messrs. P. Walters and Co., telegraph-engineers and contractors, notify that they have removed their offices from 278, Roman-road, Bow, and have entered into new premises at Blenheim-street, Chelsea, S.W.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 496.—Vol. XX. FRIDAY, NOVEMBER 18, 1887. Price 4d.

NOTES.

Not the least valuable part of the proceedings at the Society of Telegraph-Engineers last week was Mr. Charles Bright's well-timed criticism of Mr. Stallibrass's paper. Mr. Stallibrass rather overdid his advocacy of preliminary surveys for cable operations; and it was well for the meeting to be reminded by one who had evidently brought some practical considerations to bear on the subject that if it had had to wait for deep-sea surveying, deep-sea cable laying would never have been undertaken. No adequate soundings were made prior to 1879, yet most of the cables then submerged are still alive, and it would be hard to prove that the failure of those which have not survived has been due to inadequate surveys. To be of real practical utility the soundings must cover almost every inch of bottom, a case cited by Mr. Bright showing that even a very careful survey may overlook the existence of a configuration inimical to the safety of the cable.

A large section of our readers will be glad to observe that in this number we publish the first of a series of papers by Dr. Fleming on the theory of alternating currents. Dr. Fleming has undertaken, by dint of mechanical illustration and painstaking explanation of the difficulties which beset the subject, to bring the treatment within the grasp of the meanest (mathematical) capacity. To a certain extent the papers will take the form of an elucidation and a commentary upon the work of Mr. Thomas Blakesley on the same subject, which was originally published in these columns in the year 1885, but they will also include a large amount of original research of both a theoretical and an experimental character. We must add that, owing to Dr. Fleming's numerous engagements, the papers will perhaps appear at somewhat irregular intervals.

Elementary students, especially those who are interested in submarine telegraphy, will note with satisfaction that we this week commence a series of "Letters for Learners," by Mr. A. E. Kennelly, of the Eastern Telegraph Company, whose researches in the higher branches of cable testing are already widely known and appreciated.

In the matter of Ferranti *v.* Gaulard and Gibbs, we are now able to state on the best authority that the rumour to which we referred last week, and which stated that the matter had been settled out of court, is entirely without foundation.

On the whole there seems to be decided ground for encouragement in the aspect of the electrical engineering trades at the present time. The more important firms are, so far as our information extends, with very few exceptions, doing a fair business, and in some cases have quite as much work in hand as they are able to undertake. It is true that prices have been cut very low, and there is still in many cases far too much readiness to accept contracts on terms which it is difficult or impossible to account for on ordinary business principles. We have just heard on good authority that in a certain case, upon which we commented at the time, where the highest and lowest tenders stood in the ratio of something like 5 to 1, the contractor has already expended considerably more than *three* times the amount tendered for, and has not yet come to the end of his job. It would be interesting to learn the contractor's own views upon the affair, both first and last. Let us hope, however, that in this case *Experientia docet.*

Complaints of bad workmanship and inefficient engineering are still not infrequent. These invariably arise from cases where the work has been undertaken by men who have received no proper training either in the theory or practice of electrical engineering. We do not want, even in appearance, to single out any individual example for condemnation, but we happen to know of one case in particular in which a firm of self-styled "electrical engineers" consists of two partners, one of whom lately forsook a highly respectable but entirely non-technical calling—let us say the cats'-meat trade—while the other acquired his scientific knowledge and experience in the intervals of duty as—let us say a shoe-black. This illustration is but a slight travesty of the actual facts, while the people in question are doing an extensive business upon terms with which some of our best-known firms are quite unable, or at least unwilling, to compete. We are not in favour of drastic measures in these cases, even if such were possible; but in the light of facts like this (and we could multiply instances if necessary), is it to be wondered at that respectable business men should consider it highly desirable to take steps which may at least indirectly tend to mend these crying evils?

Turning to the brighter side of the subject with which we commenced the preceding note, it is satisfactory to observe the encouraging strides which are being taken in the department of transmission of power. Inquiries are numerous, and in one case we could name a leading firm will be able at the end of the present year to show a turnover in this branch of their business exceeding fourfold the amount done last year.

Digitized by Google

Another firm, who are more closely identified with storage batteries, are also making a speciality of electrical hoists, and find inquiries plentiful. In a third case, a well-known contractor is laying out plans for a central station solely—or at any rate primarily—for the distribution of power. It has long appeared to us that there are many towns, and many parts of London, where such installations would, if properly laid out, be certain to prove remunerative.

READERS of Mr. Nursey's paper on Primary Batteries (in which it will be remembered the author allows the respective inventors to speak for themselves) will kindly note that, in order to economise space, the following sentence has been omitted from the catalogue of the merits of each battery:—"The light was remarkably steady and brilliant, and of good quality." *Mirabile dictu!*

THERE is at least one kind of primary battery which appears to be a great success for domestic purposes. On Monday last a whole page of the *Daily Telegraph* was appropriated to the advertisement of a certain electropathic belt, and if in this case, as in most others, the financial merits of the ware may be estimated by the money spent on advertising it, the article in question must be a very valuable property. Seeing that there are several competitors in the field, all equally profuse in their subsidies to the press and all equally lavish in their promises to the faithful, electro-pathology is a business which M. D'Humy and others might take up with advantage. The advantage which the medical battery possesses over the rest is that, although like some of them it appeals to faith, unlike them it cannot be rejected by reason. Everybody hopes that the numberless cures ascribed to its agency are genuine; but the beauty of it is that nobody can prove they are not. We advise the friends of primary batteries to seriously consider this means of employing their idle stock. If Electricity is Life, why not lay it on to every household, storing it in the place now occupied by the medicine cupboard, and charging at so much per head?

DYNAMO men should not miss the Note on an instructive break-down which will be found further on.

AMONGST the distinguished few who evidently bring to bear a sound scientific knowledge upon the problem of lighting by primary batteries, the designer of the particular form of chromic acid cell which is described in another column will take an honourable place. It was refreshing to listen to the candid and unasked-for confession that this cell does, after all the efforts of the inventor, still possess some internal resistance, that there is still some trifling amount of local action to be apprehended, and that it does not at present afford so economical a means of domestic illumination as gas. This is the sort of thing which gives one a returning gleam of confidence in the ultimate prospects of primary battery lighting. And we may add, moreover, that so far as our observation has gone we have formed a distinctly favourable opinion as to the merits of this particular cell—at least, for all cases in which a chromic acid solution is admissible.

MR. THOMAS BLAKESLEY'S brief reference (at the Physical Society's Meeting on Saturday) to the employment of condensers with alternating current apparatus may ultimately be found to cover a point of no small practical importance. Some eighteen months ago at Mr. Frank Nalder's laboratory, at Brentford, we had the pleasure of witnessing the experiment in question, when performed by Mr. Blakesley for the first time. An alternating current machine was connected up in series with two Siemens dynamometers and a resistance coil. Between the two dynamometers the circuit was bridged across by a condenser. Mr. Blakesley had predicted that with this arrangement the current passing through the armature of the machine would be less than that passing through the resistance coil. A very marked effect of this character was at once apparent on the dynamometers. This is not the place to go into the theory of the phenomenon, which is now pretty well understood; but it may be pointed out that the condenser counterbalances, as it were, the self-induction of the coil, and thus reduces the impedance of this portion of the circuit. We believe that this phenomena has been also independently discovered by Dr. Muirhead, and everyone will remember that in Mr. Sumpner's paper read before the Society of Telegraph-Engineers and Electricians in May last the combination of capacity with inductance was elaborately discussed. But this was twelve months later than the date of the experiment now described.

IN order to avail ourselves of the property of condensers referred to above in the practical application of alternating currents it would be necessary to find some simple and economical method of constructing a condenser of large capacity. There seems no reason to doubt that the problem can be solved in a very simple manner. Clerk Maxwell was, we believe, the first to call attention to the possibility of using what may be called voltameter-condensers with alternating currents, and Mr. Blakesley, Dr. Fleming, Prof. Silvanus Thompson (and possibly many others) have all suggested or discussed the idea; but we are not yet aware that any one has actually tried it. (This no doubt arises from the fact that alternating current machines are so rarely found in laboratories.) A voltameter condenser must consist of at least ($V \div 1{\cdot}4$) cells joined in series, where V is the maximum periodic E.M.F. at the terminals. The platinum plates may be of very small size, and the liquid pure water. Under these circumstances no current can flow, but the capacity of the series will be very great. The effect is, of course, due to the incipient decomposition of the molecules of the liquid, whose relative polar directions are reversed at each alternation of the current. The arrangement may be roughly compared to a series of elastic springs which are alternately compressed and allowed to expand, the springs being always fixed rigidly at one end and free at the other, and the end at which they are fixed undergoing alternate change. It may be hoped that we shall soon hear something further on this interesting subject.

CAPTAIN SHAW'S report just issued on the destruction by fire of the Exeter Theatre places among the foremost causes of the appalling loss of life the absence of any lighting arrangements independent of the stage. This is a point on which we

Digitized by Google

have strenuously advocated reform ever since the fatal conflagration at the Opéra Comique.

It has never been our custom to make capital out of the mischances which dishearten the advocates of those forces that in various directions attempt to dispute the field with electricity. Our esteemed contemporaries, the *Gaseous Chronicle*, the *Coal Tar Gazette*, and the *Carburetted Hydrogen Calendar*, know this full well, and regard our silence with a similar gratitude. (We also at times remember an adage about "glass houses.") For once, however, we are moved to recapitulate in brief the story of a remarkable accident which occurred in the streets of Cincinnati to a tramcar on a cable line. A strand of the cable broke loose and one end wrapped around the gripper, so that the car could not be released from the cable. Another car was standing still a little way ahead, and with this the runaway car came into violent collision. The two cars tore along the crowded streets, and at length collided violently with a horse car at a crossing. All three cars were overturned, and the sudden jerk to the cable threw several more cars off the rails. Thirty or forty people were injured. While writing of tramcar accidents we may note that the story which we recently copied from a Philadelphia paper about a fatal accident to a horse from the breaking of an overhead wire belonging to the Van de Poele system has since been contradicted by the New York *Electrician*.

A good while ago we put the question to those whom it concerned, On what scientific principles can the alleged properties of a certain battery be accounted for? but no reply was vouchsafed. An independent correspondent now informs us that he has found the explanation of most of the phenomena connected with this remarkable invention, not in Clerk-Maxwell but in Thomas Carlyle. The people of this country, said the sage of Chelsea, number "twenty-seven millions, mostly fools." We feel sure our correspondent means by this that the inventor is *not* to be classed with the majority, whatever may be thought of his patrons.

While wishing all possible success to the Leamington Central Lighting Station, it is impossible to shut one's eyes to the fact that the promoters of the scheme have placed themselves in a position in which they must achieve either triumphant success or suffer disastrous failure. We are writing upon the assumption that the business is to be conducted upon ordinary commercial principles; and if it can be shown that a simple three-wire distribution can be made to pay its way in this country under a tariff of 4d. to 7d. per unit, then we shall be amongst the first and the most sincere in congratulating Messrs. Chamberlain and Hookham upon their achievement.

Milan.—The Victor Emmanuel Theatre at Milan has been supplied with an electric light installation.

Vienna.—It is reported that the Tramway Company of Vienna has entered into negotiations with an American company for the introduction of electric motors upon the whole of its lines.

Handbook on Accumulators.—Messrs. Whittaker and Co. will publish next week a third edition of Sir D. Salomons' little "Handbook on Accumulators." We learn that the book will appear in an entirely new and handy form, with illustrations in the text and much additional matter.

Proposed Telephone Cable between London and Paris.—According to the daily papers observations are being made on the French coast and in the Channel by French Government officials, with a view to laying down a new cable across the Channel, in order to establish telephonic communication between London and Paris.

Books Received.—We have to acknowledge the receipt of the fourth volume of the *Transactions* of the American Institute of Electrical Engineers, which contains the reports of six meetings held during the interval from June, 1886, to July, 1887.—We have also received a copy of "L'Electricité, Notions et Applications Usuelles," by M. Aug. Michaut.

Lecture on Electric Lighting at Newcastle-on-Tyne.—Mr. W. B. Sisling, electric superintendent of the Newcastle Exhibition, delivered a lecture on the subject of electric lighting in St. James Schoolroom, Bath-road, Newcastle, last week. The lecture was an especially interesting one, as Mr. Sisling was able to show in operation a Paris and Scott transformer and a couple of Mr. F. J. Rowan's electro-magnetic machine tools.

The Société Generale des Telephones. — The *Bulletin du Crédit*, a financial journal, published in Paris, says that owing to the constantly increasing business of the company the board of administration have decided to call up the balance of 125 francs per share. Up to the 27th October last the number of subscribers was returned as 7,589—namely, 5,271 in Paris, and 2,318 in the provinces. The capital of the company is 25,000,000 francs—say £1,000,000.

An Electrical Pilot Engine.—An Austrian lieutenant, named Giessle, of Brünn, is said to have developed an idea which is, perhaps, more strikingly original than practically useful. He proposes that every railway train should be preceded by an *avant-courier* in the shape of an electrical pilot engine—attached, we presume, by wires to the advancing train. We do not doubt that this *can* be done, but we shall be astonished if railway engineers will be at all thankful for the suggestion.

Sir William M'Arthur.—Many of our readers will learn with extreme regret that Sir William M'Arthur, who has been a Director of the Eastern Extension Telegraph Company for many years, expired under painful circumstances on Wednesday morning. The deceased gentleman, who was travelling by the Metropolitan Railway from Notting Hill Gate, about half-past ten o'clock, was taken suddenly ill when the train reached Bayswater, and died a few minutes after his removal at the Praed-street Station.

The Society of Telegraph-Engineers and Electricians.—A meeting of the above society will be held at 25, Great George-street, Westminster, on Thursday, November 24th, at 8 p.m. The following papers will be read:—(1) "On some Instruments for the Measurement of Electromotive Force and Electrical Power," by Dr. J. A. Fleming, M.A., Member, and C. H. Gimingham. (2) "Portable Voltmeters for measuring Alternating Potential Differences," by Profs. W. E. Ayrton, F.R.S., V.P., and John Perry, F.R.S., Member.

The Westinghouse "Automatic" Engine.—We note that the prospectus issued by the promoters of the Westinghouse Engine Company contains a list of over 150 of these engines employed in this country and in America for electric

Digitized by Google

lighting. The Admiralty have ten Westinghouse engines in use. Many of these have been hitherto imported from America, the facilities for their manufacture in this country not being sufficient to meet the demand. The new company is therefore floated with the idea of undertaking the manufacture on a larger scale.

Bournemouth.—With reference to a *conversazione* of the Bournemouth Society of Natural Science, held at Ascham House on the 8th inst, the "Bournemouth Visitors' Directory" of the 12th says:—"Mr. Lynd fitted up twenty incandescent lamps, which were lighted by fourteen of the Electrical Power Storage Company's accumulators. These cells were charged at the Millwall Works, and sent down from London for use at the *conversazione*. The system of storage of electrical energy was explained to a number of gentlemen, who appeared to take an interest in electric lighting."

The Lighting of the Isthmian Club.—We were indebted to a member of the above club for a note in our last issue concerning the recent introduction of electric light, in which a portion of the work was credited to Messrs. Woodhouse and Rawson. A correspondent now informs us that this is inaccurate, and continues: "The brass fittings used in the billiard room and in some of the passages were supplied and fitted up by Messrs. Verity and Sons, but the fittings for by far the greater number of lights, which are constructed altogether of wrought iron and are exceedingly handsome, were made by Messrs. Starkie, Gardner and Co., and installed by the United Electrical Engineering Company."

The Ries "Combination" Conduit.—Mr. E. E. Ries, of Baltimore, proposes to kill two birds with one stone. He suggests—and, of course, patents—an arrangement in which in an electric railway on the "conduit" system the whole of the space on each side between the central conduit and the rails is utilised for telegraph, telephone, or electric lighting conductors. To this end the space in question is filled to the depth of 18in. or 2ft. with numerous paper tubes of different diameters, which are set in concrete. Manholes are provided at frequent intervals. The idea is that the tramway company should provide the conduits and let them out to the telephone or electric light companies.

The Electric Lighting of the Recent American Exhibition.—An error occurred in the note under this heading in our last issue. The engines used for driving the Thomson-Houston dynamos were three compound undertype engines, with boilers above, of 10 horse-power nominal, 30 horse-power nominal, and 50 horse-power nominal respectively, and a fixed compound engine with separate boilers of 60 horse-power nominal, making an aggregate of 150 nominal horse-power, which ought therefore to be capable of running up to about 450 indicated horse-power. There were 285 arc lamps in use, taking each 75 to ·8 horse-power, so that about 228 to 230 horse-power was actually used.

The Brussels-Paris Telephone Line.—MM. Manne, of Curheim, write us with regard to the report in the French journals (to which we referred in a recent issue) as to the destruction of a portion of the Brussels-Paris telephone line during the recent gales. MM. Manne are interested in the matter, inasmuch as they supplied the phosphor-bronze wire which is used as far as the Belgian frontier. They assure us that the only foundation for the report in question arose from the fact that the coping-stone to which the wire was attached at the Brussels Bourse (where the line terminates) was torn away and fell into the street, but even then the wire did not break. We are further told that not one phosphor-bronze wire in the Belgian telegraph service was broken during the gales. A letter from the Brussels Ministry of Posts and Telegraphs is also enclosed, confirming these statements. We are very pleased to note this satisfactory proof of the reliability of this class of wire.

An Extraordinary Mishap at a Central Lighting Station.—At a central lighting station in a certain town not far from London a very curious accident recently occurred which very nearly caused the entire breakdown of a series-wound high-tension dynamo on a circuit of 2,000 volts. In order to see whether a pole-piece was getting hot an attendant unwisely attempted to spit upon it. We say unwisely because, not being a Yankee he had not acquired the art of spitting straight, and missing the mark, the field coil received the full benefit. The machine in question is an elderly one, and possibly the coils wanted a new coat of varnish—anyhow, in a very few minutes the cotton covering commenced to char, and a small arc began to play across the wire. It wanted still an hour to the time when the machine should stop running. By dint, however, of incessant "dabbing" with a handful of asbestos the arc was kept within limits until the evening's work was over. It was then found that the insulation had been destroyed to the depth of four layers of wire. MORAL: This method of testing the temperature of pole-pieces requires some practice, and should only be undertaken by an expert.

Cancelling of the Bell Patent in Austria.—The efforts of the Telephone Company of Austria to get the Bell Patent cancelled have at last been successful. Their manager, Mr. R. Howard Krause, believed this possible from the commencement, and with the assistance of Mr. Otto Schaffler the company has been the means of securing free trade in telephones in Austria. The result of the decision of the Austrian Ministry of Commerce, and the Hungarian Ministry of Agriculture, Industry and Trade, dated October 28th, 1887, seems to be that all those clauses of Bell's Patent which refer to the telephone are cancelled, only those referring to the multiplex telegraphy being allowed to stand. Certain clauses were cancelled because the Telephone Company of Austria was able to prove prior publication, and others were cancelled because the company proved that they embodied scientific principles which, according to Austrian law, cannot be the proper subject of a patent. The Telephone Company is naturally very jubilant over its success, and is preparing for a large development of its enterprise.

Important Search-Light Experiments at Newcastle.—During the last fortnight of the life of the exhibition a search-light, constructed by Messrs. Clarke, Chapman, Parsons, and Co., was exhibited on the watchman's tower of the old Tyne Bridge, and created a great deal of interest in the district. The lamp took a current of 100 amperes at 60 volts, so that it was nominally a 24,000-candle light. On one evening an ambulance competition was held in the grounds, and the dais on which the competitors did their work was illuminated by the search-light; but the most interesting experiments with the light were carried out by Captain Oswin Bell. Between Newcastle and Tynemouth high land intervenes, so that signals cannot be flashed direct between the coast and Newcastle. Captain Bell wished to see whether signals flashed into the sky could be read across the higher land. Accordingly, men were stationed at North Shields, Tynemouth, and along the coast as far as Blyth. The evening was very unfavourable, as there was a haze near the ground, a clear sky, and a bright moon; but Morse signals could be read in the sky at all the stations. The maximum elevation of the light was about 150, but at Blyth it was best seen at a much

Digitized by Google

lower elevation. The distance between the exhibition and Blyth in the straight line is about 11½ miles.

Telephone Apparatus and the Spanish Tariff.—The Spanish Customs journal, *El Eco de las Aduanas*, of Nov. 7th, publishes a royal order setting aside a decision of the Customs Arbitration Board respecting the application of the Customs tariff to imports of telephone apparatus. It would appear that a consignment of about 7cwt. (330 kilogs.) of telephone apparatus, made of fine wood with brass fittings, was presented at the Irun Custom-house, and declared under Section 180 of the tariff, which applies to "fine wood manufactured into furniture or other objects, turned, sculptured, polished and varnished," the duty upon which, for treaty nations, is at the rate of 13s. 6d. per cwt. (nearly). The declaration was refused, and Section 181 of the tariff was imposed, the goods being considered as "fine wood manufactured into the same articles, gilt; and those veneered with mother-of-pearl or other fine materials and designs of metal," &c., the duty upon which was, for treaty nations, no less than £2. 1s. per cwt. (very nearly). This decision was appealed against, and the royal order now issued sets forth that as the metal buttons attached are for the purpose of joining the wires and to permit the apparatus to work, and that as the apparatus is similar to electric bells, which have already been passed under Section 180, it is ordered that the telephone apparatus in question shall be admitted under the lower rate of Section 180 as in the first instance.

The Cost of Electric Light Fittings.—Mr. Nelson Haxell, of Haxell's Hotels, London and Brighton, writes as follows to the *Daily News*:—"Nothing prevents the immediate universality of house-to-house electricity and our happy deliverance from gas with its compound attendants of disease, dirt, villainous filthy smells, danger, and a price per thousand feet absolutely absurd at its present prime cost of production, but the absolutely prohibitory charges for what Hammond and Co. call 'the installation.' Could I only get installation at even a fair rate I would lay on the electric light in both my hotels immediately. Let us go into this. In my Brighton hotel I had arranged all costs of supply, wire and lamps—of which more anon—when they actually demanded of me an additional sum of £20 to give me unlimited supply, day and night, without which in my business it would be useless. In other words, not having the fear of competition before their eyes they insisted I should find £20 capital to enable me to be a good customer to them. So exit electric light for the present. Here in the Strand an electric company, beloved of Hammond and Co., have sent me in an estimate for installation amounting to £267. 10s. for wires and lamps, a rental of £15 per annum for fittings; one need not go into the calculation of the cost of silk-covered wire. . . . This, Sir, is a round unvarnished tale; and until electric lighting companies can see that it is to their interest to reduce them, these prohibitory charges will prevent the introduction of house-to-house electricity and the 'good-bye at the door' to gas, with all its dangers, dirt, and dearness."

Leeds.—On the proposal for the reappointment of the Electric Lighting Committee of the Leeds Corporation, Mr. E. Wilson spoke in opposition. He submitted that of the money granted to the committee for the provision of the electric light £3,965 had been squandered on a system of lighting which could have been got for half the money.—Alderman Emsley contended that there was nothing to show for the money which had been expended. He believed that £6,000 of the £10,000 granted had been spent.—Alderman Tatham reminded the council that when the committee was appointed electric lighting was in its infancy, and had been constantly undergoing improvement. He admitted that their electric installation could now be obtained at half the cost, but it could not have been set up for that amount when it was provided. He submitted that there had been no waste of money, and urged that the committee should be again appointed to watch the course of events.—Mr. Harland opposed the appointment of the committee.—Alderman Baker pointed out that a good deal of the money had been spent in preventing companies from coming into Leeds and pulling up the streets in order to provide electric lighting, and in obtaining information with reference to the best system. Then there were the costs in connection with the lawsuit which was commenced in reference to some part of their installation. At the same time it appeared to him that there was nothing now for a committee to do.—Alderman Spark pointed out that their scheme of electric lighting included the lighting of the new Fine Art Gallery, and if the committee was not reappointed that matter would fall into confusion.—Mr. Hardwick, chairman of the committee, having explained the course adopted by that body, and vindicated its action in not going on experimenting, the council voted on the question, with the result that the committee was reappointed.

Experiments on the Working Model of an Electric Boat.—Some interesting experiments were made at the Liverpool Exhibition by Messrs. Cox, Robinson and Co. on a working model of an electric boat, the object being to test its efficiency when in the water as compared with the power developed by the motor when running out of water. The model was seven feet in length by eleven inches beam, and eight inches in depth. It was propelled by a series-wound motor of the Siemens type, having a resistance of 6 ohms, and weighing 14lb., driven by five E.P.S. accumulators, whose capacity equalled 17 ampere hours; maximum safe discharge, 10 amperes. The total weight was 41lb., that of hull and fittings being 26lb. The motor was first allowed to run with the boat out of water. Tooth gearing was used between the motor and the screw-shaft, the ratio of the gearing being four to one. The results were as follows: Revolutions of motor, 1,910 per minute, with a current of 4·9 amperes. On placing the boat in the water the speed of the motor fell to 1,240, and the current rose to 7 amperes. The boat travelled at the rate of 64 yards per minute. This result being unsatisfactory, the motor was afterwards coupled direct to the shaft, the same screw and battery being used. The boat being taken out of the water, the revolutions were 2,100, and the current became 4·3 amperes. This showed an absorption of 6 watts, due to the gearing. On putting the boat in the water the revolutions fell to 760, the current rose to 8·4 amperes, while the speed of the boat was 129 yards per minute. This is a considerable improvement, when the increase of speed is compared with the increase in expenditure of power. The above data can be regarded as being very nearly correct—say within 5 per cent. A variable resistance was used in circuit for the manipulation of the speed. Messrs. Cox, Robinson and Co., point out that although a steam engine would develop more power from the same total weight in a boat of this size, the coal it would carry would not enable it to continue running for more than 35 minutes, whereas the accumulators would last for two hours without recharging. The fact that the motor fields were not saturated would admit of more cells being added to the batteries, and the output being increased thereby.

NOTES ON ALTERNATE CURRENTS.

BY J. A. FLEMING, M.A., D.SC.

Both in hydro-dynamics and in electro-dynamics the condition of fluid flow or electric currents may be considered either in the *variable* or in the *steady* condition. In the former case the strength and direction of the electric currents or the fluid velocity is changing at every instant; in the latter case, it has settled down into a permanent form. The questions involved in dealing with the variable state present greater difficulties than do problems in steady flow, for the reason that the notions of *time* and *inertia* enter into these in a way in which they do not when that flow has reached a steady condition. We shall in these notes examine in an elementary manner some features of electrical flow when periodic, fluctuating, or variable. When a mass of water is in motion at any instant, a particle of water selected for examination has a particular velocity in a particular direction. This may be represented by a straight line drawn from that point representing its velocity in direction and magnitude. Similarly, if electricity is flowing through the mass of a conductor in any manner, it is possible at any point to draw a *vector* or line representing at that instant the direction and magnitude of the current at the point from which the line is drawn. Lines drawn in the mass of a conductor such that the flow at every point is along or tangential to these lines are called *stream lines*. If a surface is supposed described in the mass of the conductor everywhere perpendicular or orthogonal to the stream lines, such a surface is called an equipotential surface. Let it be supposed that such a surface is drawn in the mass of a conductor through which a current is flowing.

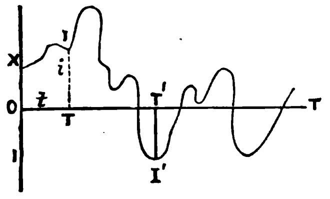

FIG. 1.

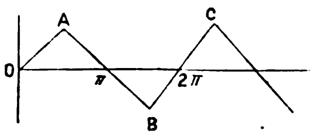

FIG. 4.

In the first place, let us make the supposition that the flow has reached a steady condition. The stream lines are then fixed. Let any area be drawn on the equipotential surface, and let it be divided up into units of area. If the quantity of electricity flowing through each unit of area is the same, and if, moreover, it is the same for each unit during each succeeding instant of time, the current is said to be steady and to be uniformly distributed. The quantity flowing per unit of time through any area is the numerical measure of the strength of current *at* that section of the conductor, and the quantity flowing per unit of time through a unit of area is the measure of the density of current over that unit of area. If the distribution of current and strength is not uniform we can only express them at any time and place by calling to aid the language of the differential calculus. If $d\,s$ be a small area described on an equipotential surface, and if $d\,q$ be the quantity of electricity which flows in a small time $d\,t$ through that area $d\,s$, then if i is the strength of the current and d the density of current at the centre of that small area, in the limit when the area becomes vanishingly small

$$i = \frac{dq}{d\,t} \text{ and } d = \frac{i}{d\,s}.$$

To fix our ideas, let us now suppose the flow to take place through a cylindrical conductor, such as a wire, in which at positions sufficiently remote from the ends the stream lines will be parallel to the axis of the wire and the equipotential surfaces perpendicular to it.

Consider any one section, and let the flow across this section be variable both in strength and direction—that is to say, let it vary in the quantity of electricity which flows across that section in each succeeding instant, and let the flow be first one way and then the other, varying in any manner, however irregular. We can now represent graphically the state of things as regards electric flow at that section by means of a *current curve*. Take a horizontal line (Fig. 1) to represent the uniform flow of time. At every instant let an ordinate be drawn to this line, representing the strength of current flowing that section, and let it be drawn above + or below –, according as the direction of the flow is to the right or to the left. Accordingly, if time begins to reckon from O, after the lapse of a time O T the current is +ve, and is represented by a line T I. After the lapse of a time O T′, the current is –ve, and is represented in strength by a line T′ I′.

This curve may be called the current curve, and it is obviously a single-valued function—that is to say, corresponding to a given time the current can only have one value. The curve can never cut itself or double back.

In Fig. 2 is represented a curve such that there are five different values of the ordinate of the curve corresponding to one value of the abscissa $o\,x$. In Fig. 3 is represented a single valued function, such that there is only one value of the ordinate $x\,y$, corresponding to a given value of abscissa $o\,x$.

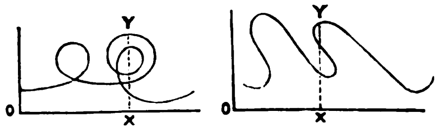

FIG. 2.
Multiple valued functions.

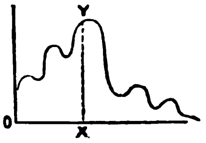

FIG. 3.
Single valued function.

Fourier was the first who enunciated the remarkable mathematical theorem now known as "Fourier's theorem." Generally stated it is as follows:—Any single valued function can be expressed as the sum of a series of terms, each one of which is the sine or cosine of an angle multiplied by a constant. Stated in other words, this amounts to saying that the equation to any such curve can be found in the form of an infinite series of terms, each one of which is the sine or cosine of an angle multiplied by a constant term. The most remarkable part of Fourier's method is its power to represent in this form the equation of lines made up of pieces of straight lines. Take the case of a line O A B C, &c. (Fig. 4), made up of lines inclined at angles of 60deg., the length of each line being $2\,\pi$ units of length. Then it can be shown that the equation to the broken line O A B C, &c., is the series

$$\frac{4}{\pi}\left\{ \sin x - \frac{1}{9} \sin 3\,x + \frac{1}{25} \sin 5\,x - \&c. \right\}$$

or is an expression formed of the sum of a series of terms, each one of which is the sine of an angle multiplied by a constant term. There is another mode of viewing this analysis which makes it especially applicable in dealing with many physical problems. Suppose a circular disc (Fig. 5), with a pin at its centre, O, and pivoted so as to revolve round an excentric point, C. Let a T bar moving in guides and having a slot in the cross-piece be so fixed that the centre pin O is constrained to move in the slot. Furthermore let the point C round which the disc moves be fixed to some support in the line of the bar A B produced. If the excentric is compelled to move round C, the extremity of the bar A will move backwards and forwards with a motion called a simple harmonic motion.

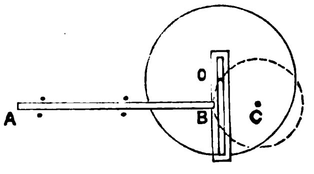

FIG. 5.

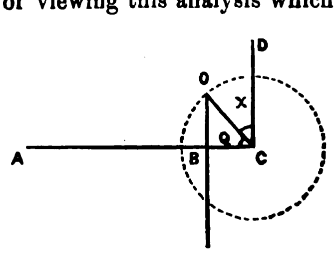

FIG. 6.

For it is clear the point O (Fig. 6) is compelled to move in a circle round C as a centre, and hence the distance of the point A from C at any instant is the length of the bar A B *plus* the length B C, which is the projector of O C on the line A C. The point B therefore executes a simple vibration to and fro along

Digitized by Google

the line A C as O moves round, and the point A imitates the motion of B. If the angle O C D is called x and the radius O C r, then the length B C is $r \sin x$, and the displacement of A at any instant from its mean or middle position has the same value. The motion of A is called a simple harmonic motion, and the above excentric and T bar is a mechanical device for compelling a point to describe a simple harmonic motion (abbreviated into S. H. M.). If such an harmonic motion be executed by point A (Fig. 7) whilst at the same time a strip of paper, S S′, is caused to move uniformly in a direction perpendicularly to the line A B, a tracing point fixed to A will describe on the paper a curve such that the ordinate A Y is proportional to the sine of the abscissa X Y, or the equation to the curve will be of the form $y = a \sin x$, a being some constant.

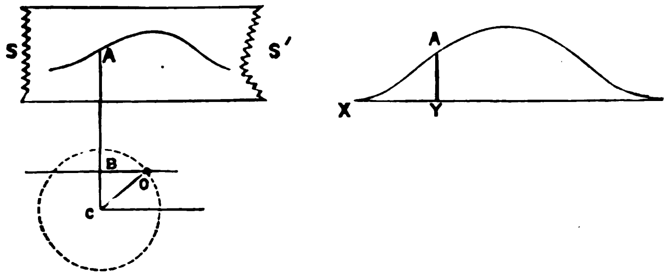

Fig. 7.

By combining together two similar pieces of mechanism it is possible to construct a machine which can add together graphically two simple harmonic motions in the same line, but of which the phase angles x are different, and the amplitudes a also. This can be accomplished in the following manner:—

Let a cord pass over four pulleys (Fig. 8), two of which, F_1 F_2, are fixed in space, and two, M_1 M_2, can be made to rise and fall in vertical lines with a simple harmonic motion. If the cord has one end, B, fixed and the other end, A, free, it is easy to see that if either the pulley M_1 or M_2 rises and falls along a vertical line and the cord is just kept tight, the free end A will be displaced by an amount equal to twice the displacement of M_1 or M_2, and as M_1 or M_2 moves up and down with a S.H.M., the free end of A will also execute similar vibrations. If M_1

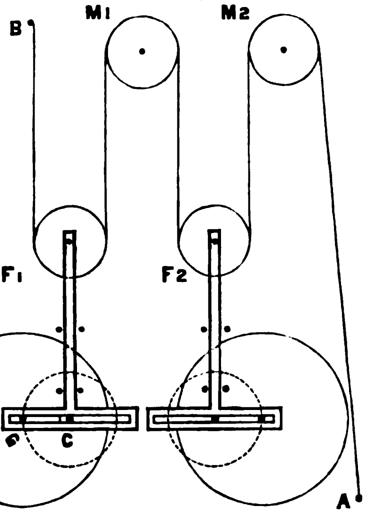

Fig. 8.

and M_2 move together the displacement of A at any instant is proportional to the sum of the displacements of M_1 and M_2. By providing the end A with a tracing point and moving under it uniformly a sheet of paper in a direction perpendicular to the direction of motion of A, it will describe a curve, of which the equation will be of the form

$$y = a \sin x + a' \sin x',$$

a and a' being the amplitudes, and x x' the phase angles of the two motions of M_1 and M_2 respectively. This apparatus, or one of similar principle, has been devised and employed by Sir W. Thomson in his tide gauge analyser. It will be evident from the foregoing explanation that a machine can be constructed capable of causing a tracing point to move to and fro across a uniformly flowing sheet of paper, with a motion compounded of a number of simple harmonic motions of different amplitude and phase taking place in the same straight line.

If, then, any single valued function is graphically represented —that is to say, any such curve as in Fig. 1—we see that this curve may be described by a point which moves horizontally with a uniform velocity, whilst at the same time it executes in a vertical direction a movement which is the sum of a number of simple harmonic motions superimposed upon one another.

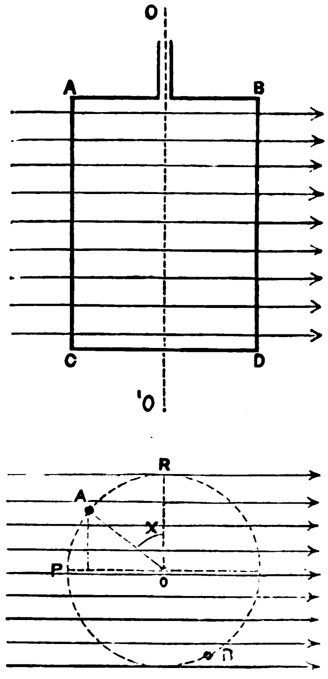

Fig. 9.

The combination of these two rectangular motions causes the point to describe the curve considered.

Fourier's theorem leads to many physical conclusions of great importance. In acoustics it shows, for instance, that however complicated may be the motion of an air particle in a mass of air through which sound waves are being transmitted, it can be resolved into the sum of a series of motions such as would be produced by the action of tuning forks, each of which gives rise to a motion in the air particles of the nature of a simple harmonic vibration. Helmholtz actually realised this in his synthesis of vowel sounds. We can in a similar manner synthesize by the superposition of simple harmonic electric currents any form of variable current, however complicated.

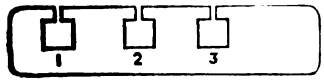

Fig. 10.

Let A B C D (Fig. 9) be a rectangular frame conductor, able to revolve round a vertical axis O O′ in a uniform magnetic field. The adjacent figure represents the same in plan. If the frame revolve round the axis O O′ the total electromotive force acting round the circuit is numerically the same as the time rate of change of magnetic induction through the circuit. If H is the field strength, l the length of the side, A C and k the length of the side C D, and x the angle which at any instant the plane of the frame makes with a plane drawn at right angles to the lines of the field, then the magnetic induction through the frame is the product of H, and the apparent size of the frame, as seen along the direction of the lines of the field, or is equal to $H l k \cos x$.

Digitized by Google

If the area of the frame is A, the magnetic induction is H A cos x. Hence the effective electromotive force acting to produce a current in the circuit is

$$\frac{d\,(\mathrm{H\,A}\cos x)}{d\,t} = \mathrm{H\,A}\sin x\frac{d\,x}{d\,t}.$$

If the angular velocity remains constant, the effective electromotive force will be simply proportional at any instant to the sine of the angular displacement of the frame from its initial position. Hence, such a frame produces a simple sine variation of electromotive force. Let a series of such sine inductors be joined up on one circuit (Fig. 10), each capable of being regulated as to angular velocity, and imagine these to revolve in magnetic-fields of equal strength. If the sine inductors are originally set with the plane of their frames at certain different but fixed angles to the planes at right angles to the fields of force in which they revolve, they must be supposed to maintain these relative positions during their revolution. Accordingly the effective electromotive force in the circuit, when they are all joined up in series and set revolving, is represented by a function

$$e = \mathrm{A}\sin x + \mathrm{A}'\sin x' + \mathrm{A}''\sin x'' + \&c.;$$

and by Fourier's theorem any possible periodic variation of e which, graphically described, is a single valued function can be produced by suitable values of the constants and phase angles.

The converse of the above is also true. Let there be any alternate current machine producing in a circuit an electromotive force, and therefore a current varying periodically according to any law. This kind or form of current could be exactly imitated by removing the given machine and substituting a series of sine inductors coupled in series and arranged so as to each produce a simple sine varying E.M.F., the respective sine currents having different phases and amplitudes, but being superimposed upon one another.

LETTERS FOR LEARNERS.

By A. E. Kennelly, Electrician, Eastern Telegraph Company.

CHAPTER I.—The Nature and Sources of Electricity.

The Galvanic Battery.

1. Notwithstanding the numerous applications of electricity to the most varied purposes, our knowledge of its nature remains of the most scanty description. In the earlier stages of investigation it was supposed to have a material existence in the form of an extremely attenuated fluid that could readily permeate conducting substances, but which found obstruction in passing through non-conductors; in the same way that liquid might pass freely through fibrous material, but be completely arrested by a densely solid barrier. Hence the terms "Electric Fluid," "Current," &c., which are still retained, not only on account of their widespread acceptation at a time when their application was more accredited, but also for the convenience with which they serve to connect our ideas in dealing with the more intricate conceptions of modern theory. There is, as we shall see, considerable analogy between the laws of the flow of water and the laws of the transmission of electricity; but in employing the terms suggesting fluids it is necessary to remember that they are only convenient symbols by which we represent and express a totally different class of phenomena.

2. It is now generally agreed that electricity is altogether immaterial in its nature, but is an inherent property of matter, through the medium of which, as with heat, gravitation, or chemical affinity, matter may acquire energy and exhibit force. This conclusion is supported by a variety of considerations. For example, if electricity were matter we should expect it to exert gravitation like all other known forms of matter, but no one has ever been able to detect any increase in the weight of a condenser after charging it. On the other hand, every evidence of the presence of electricity, since its very first recorded discovery by Thales, in the attractive power of rubbed amber, has been, and is, through some manifestation of force; while it is always found that the production of a certain quantity of electric force requires the expenditure of a corresponding quantity of energy in some other form. Thus, to obtain electricity from a frictional machine or a dynamo, we have to turn the handle of the one or the armature of the other, and if we leave out of consideration the energy wasted in friction and heat, the power of the electricity produced will be the exact counterpart of the power mechanically expended in the turning process.

3. When we obtain electricity from a battery, however, we expend no power in direct mechanical action, but we find zinc and other chemicals consumed. In this case it is chemical force and energy of combination which is expended. The zinc combines with the oxygen of the water in the cells, and is thus practically burnt; while for every grain weight of zinc thus usefully consumed a corresponding definite quantity of electric power is generated.

4. In different kinds of batteries the same weight of zinc usefully consumed may yield very different quantities of electrical energy, owing to the fact that the chemical affinity of the elements varies in different combinations of metals and solutions. The greater the resulting chemical affinity, the greater will be the energy expended in the union of a given quantity of the elements, and the greater the corresponding quantity of electrical energy developed—in other words, the greater the *electromotive force* of the cell. This electromotive force is conveniently expressed by the abbreviation E.M.F., and is practically measured in definite units, called *volts*.

5. A good type of galvanic cell should therefore fulfil the following requirements :—

(1.) The total useful chemical affinity, and thus the E.M F., should be as great as possible and constant under all rates of current supply.

(2.) None of this energy of affinity should waste itself in forming combinations while the cell remains idle. In other words, there should be no loss of material by local action.

(3.) The cell should offer in its own elements and solutions as little obstruction as possible to the liberation of the electricity it develops—that is to say, its internal resistance should be as low as possible.

(4.) The materials for its consumption should be cheap and readily obtainable.

(5.) The cell should require no inspection or supervision to keep it in good order until all the energy of its chemical affinities is exhausted.

(6.) The form and dimensions of the cell should be convenient, and no noxious chemical products should be formed in it by action.

No battery fulfils all these conditions with any degree of completeness, but we may discuss one or two of the more general forms and compare them by this standard.

6. The simplest and typical form of cell consists of a plate of zinc and a plate of copper plunged in water. As pure water is not a very good conductor, it may with advantage be acidulated, or rendered saline by the addition of common salt. No electrical action takes place if the metals are pure as long as the plates are kept apart, but the moment that they are brought into contact, either in the water or above its surface, a current will immediately be generated. It is not necessary that the plates themselves should be made to touch each other, for the wire F G H (Fig. 1), usually copper connecting wire, may be considered as an extension of the copper plate, making contact with the zinc at the point H.

7. The contact of these two metals at the point H is said to establish a *difference of potential*, and to be the primary source of the E.M.F., although the explanation of this observed fact cannot be said to be known. Difference of potential is with electricity precisely like what difference of level is with water; and just as water flows in virtue of difference of level from the higher to the lower, and the greater the difference of level the greater the force or head of water, so electricity flows in virtue of difference of potential from the point of higher to the point of lower, and the greater this difference of potential the

Digitized by Google

greater the electromotive force. In fact, difference of potential constitutes electromotive force.

8. The difference of potential set up by the contact of the copper wire with the zinc plate at H (Fig. 1) causes the zinc plate to become positive and the copper wire negative; in other words, the zinc takes the higher potential and the copper wire the lower, and an electromotive force is thus determined generating a current from the zinc plate to the copper wire. There are obviously two paths by which this current from B can reach H—one direct across the junction A, the other circuitous through the water, copper plate, and wire, B E F G. The current is prevented by the E.M.F. itself from taking the direct path across the surface of contact, and is therefore compelled to take the second and longer route. It is therefore important to notice that the zinc plate, being positive to the copper wire as regards the junction H, is usually spoken of as the *positive element*, and hence the copper as the *negative element* of the cell; while externally, because the current is flowing in the wire F G H from F to G, the potential at F, though lower than that at B or E, is higher than that at H, and is therefore positive relatively to H. Consequently, on cutting the wire at G, the portions H G on the zinc and F G on the copper are called the *poles* of the cell, and F G being positive to H G is called the positive pole. So that, while the zinc is internally the positive element, the copper is externally the positive pole.

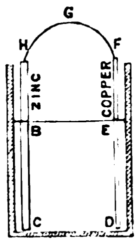

Fig. 1.

9. If the difference of potential due to establishing contact at H were temporary and unsustained, the current flowing from B round to H would re-establish equilibrium and cease, just as the flow of water from a higher to a lower level tends to equalise the level; but it is generally considered that the current having once started is maintained by the chemical energy of the materials in the cell. Thus in our typical case represented in Fig. 1, after the current has commenced to flow, bubbles of gas will be seen to form on the copper plate, and to rise to the surface of the water. The water is being decomposed into its constituents, oxygen and hydrogen, the oxygen attacking the zinc and uniting chemically with it, forming a coating of zinc oxide on its surface; while the hydrogen, not being able to form any chemical combination, forms in bubbles on the surface of the copper plate, these bubbles rising to the surface of the water as their buoyancy overcomes their attraction to the metal. If the water has been previously acidulated by the addition of a little sulphuric acid, the insoluble coating of oxide on the zinc plate is converted by the acid into sulphate of zinc, which, being soluble, disappears into the water, leaving the fresh surface of the zinc free. Thus in the action of the cell we find that the zinc plate is gradually consumed and loses weight, sulphate of zinc accumulates in the solution, the copper plate undergoes no change, but bubbles of hydrogen rise on its surface.

10. Such a cell would fairly satisfy all the requirements specified above except the first two; in fact, this was the original form of the galvanic cell, and the ancestor of all the numerous types in modern use. Its great weak point lies in its low and variable E.M.F., for the hydrogen bubbles in contact with the copper plate set up a counter E.M.F., opposing the current maintained by the original E.M.F. due to the contact of the zinc and copper. This phenomenon of gaseous contact and counter E.M.F. is commonly called *polarisation*, and the amount of polarisation varies with the quantity of hydrogen in contact; consequently, the resultant E.M.F. is very variable. The first attempt to overcome this difficulty was roughening the surface of the copper plate, so that the bubbles of gas were more quickly liberated upwards, and thus the limits of the variation in the E.M.F. were kept more confined. The early Smee cells were of this nature, but it was not until the invention of the Daniell cell that any approach to constancy of E.M.F. was arrived at.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

A large number of replies to our recent circular have been received, but, as they continue to reach us by every post, we postpone until next week an analysis of the contents.

ELECTRIC TRACTION ON THE WEST METROPOLITAN TRAMWAY.

We have recently visited the West Metropolitan Tramway Company's depôt at Richmond to inspect a new self-contained electric tramcar. This car presents no features of especial novelty, but we may congratulate the engineer on the workmanlike manner in which the general details are carried out. The car is of the ordinary two-horse type with outside seats, with the carriage raised somewhat so as to make room for the motor and gearing beneath the flooring. The rolling wheels are thus larger than usual, being 30in. in diameter. The motor is an ordinary Siemens horizontal machine, with an 8in. armature. Two sets of brushes are used, one for running in each direction. They are shifted by levers worked from either end of the car. The motion seems to be very easy and quite positive—a matter of no little importance. The motor and gearing are carried on an iron framing bolted to the sole bars of the under carriage. The gearing is double and is of the Julien type. The first transmission is made by a cotton and silk rope about $\frac{3}{8}$in. in diameter, which works in grooved wheels. The tension of this rope is adjusted by an idle pulley. The second transmission consists of a chain and sprocket wheels running in an oil bath. The gearing runs nearly noiselessly, and appears to work well, although it is perhaps doubtful whether the rope will be entirely free from slip. The accumulators are placed, as usual, under the seats; they are in trays of twelve cells each, four trays being used on either side of the car. This gives 96 cells. Each cell consists of a vulcanite box, open at the top, and contains 15 plates. These accumulators are by M. Philippart, and in the absence of any data as to their performance we may say that they certainly looked very healthy, and showed no signs of buckling or sulphating. The grid is of the E.P.S. type, as regards outside appearances at any rate. In each tray the twelve cells are coupled in series, and the end terminals are joined severally to two metal strips securely fastened to the bottoms. They are placed in the car on brass-capped runners, so that the act of putting in a tray makes electrical connection with the cells in it. These runners are joined by cables to a Julien commutating switch at either end of the platform, and by rotating a wheel on the top of this switch the cells can be made into combinations—1st, all in series; 2nd, two in series and two in parallel; 3rd, four in parallel. These arrangements give three different E.M.F.'s, 192, 96, and 48 volts respectively, and are used according to the speed required. An efficient hand brake is provided. The line between Richmond and Kew is very level and well laid, and should not have a tractive resistance of more than 30lb. per ton in an ordinary way. The difficulties to be met here are very light.

Electrical traction does not seem to be making much progress in London, though the matter is now certainly beyond the experimental stage. We shall be glad to hear that the West Metropolitan Company see their way to convert their plant. The present series of experiments are being carried out under the direction of Messrs. Christopher James and Co., engineers, of Laurence Pountney-hill, E.C.

"THE ELECTRICIAN" *can be obtained in America from* D. VAN NOSTRAND, *23, Murray-street, and 27, Warren-street, New York.*

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.*
It has the largest circulation of any English Electrical paper, and circulates all over the World.

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December next.

The EDITOR *will be glad to receive new names for insertion in the* DIRECTORY *as soon as possible, but not later than December 1.*

All particulars relating to Advertisements will be at once forwarded, on application.

VOLUME XIX.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

THE GOVERNMENT AND THE CHANNEL CABLES.

With much circumstantiality and a great parade of authenticity the *Central News* published on three succeeding days last week intelligence relating to the negotiations then going on between the French Government, the Submarine Telegraph Company, and the British Post Office, which seems to have been received by the Press and the public of this country as something of considerable importance. In reality the gist of the whole matter was contained in the opening sentence of its communication on Thursday, when the *Central News* announced that "the Government have resolved to keep under their direct control all telegraphic cables between Great Britain and France, Holland, Belgium and Germany as soon as the present concessions have expired." Since the taking of Holland by the Dutch, perhaps no piece of news in modern times has been more superfluous than this. That the British Government had resolved on that course has been known for many years past. Whether they will be able to act on their resolution is quite another matter, and one on which the omniscient news agency throws very little light. We are told that in respect to France a difficulty has arisen because the Submarine Telegraph Company have obtained the consent of the Government of that country to an extension of their concession for a further period of fifteen years; and it is intimated that the British POSTMASTER-GENERAL has vetoed the arrangement, or, to be more exact, has declined to be a party to the renewal. Probably nobody expected that he would be a party to it; what remained in doubt was that his veto will be effectual, or that his not being a party to the arrangement would prevent its being carried out, a doubt which the information furnished by the *Central News* has not in the least cleared up.

Digitized by Google

This essential feature in the case is rendered not less obscure by Sir ARTHUR BLACKWOOD'S disclaimer, which in due course, like all official denials, appeared two days later, when the *Central News* had delivered its budget. The POSTMASTER-GENERAL directs him to say that the statements which had recently appeared in the Press were entirely unauthorised, and that the information conveyed was in many particulars inaccurate and misleading. On this we may remark that all such statements usually are inaccurate and misleading, whether authorised or not, the object of their publication being generally to give a bias to public opinion, and a consequent fillip to negotiations still pending. We have no reason to doubt that the news agency responsible for these statements had them from "the highest official sources"—a discount being allowed on the superlative. Indeed, the communication betrays in several particulars an official origin, and could hardly have been evolved from the inner consciousness of the *Central News*, though a great deal of amplification and rash conjecture have been obviously permitted in the editing. The *Central News* sticks to its guns; and naturally does not reveal the source, whether highest or lowest, of its inspiration. The ball has been set rolling; and from the brief now furnished by this enterprising agency in the case of the POSTMASTER-GENERAL *versus* the Submarine Telegraph Company and the French Government, doubtless many powerful discourses will be delivered when the subject is riper for discussion. There is no immediate hurry, however. The Company's concession does not expire until the year after next, and meanwhile we may hope that some friendly arrangement may be arrived at.

Nevertheless, we cannot believe that the statements which have now obtained publicity are calculated to pave the way for an amicable settlement. Some of them at least have an opposite tendency. The lofty, dictatorial tone, the insular and narrow conception of the situation, and the patronising spirit with which the Post Office is credited in offering to buy the Company's cables at "an electrician's valuation," but refusing anything for the "goodwill," are not exactly the methods of good diplomacy when something is risked by neglecting them. And that there is some risk seems to us undeniable. The facts of the case appear to be that the Submarine Telegraph Company, which has held an exclusive concession for English cables on the French coast since 1851, has obtained a promise of renewal for another term of years, but that the promise has not yet been confirmed by the French Government; and that the English Government are doing their utmost to prevent its confirmation. There is really nothing to be said against any of the parties to this triangular duel. The Company is entitled to get what it can, the French Government to give what it pleases, and the English to checkmate both. But it must not be supposed that the final settlement rests with any one of the parties—at least, we shall be greatly surprised if it does; and if the French Government, with its client, the Cable Company, chooses to be obdurate, things may be made unpleasant all round. If rumour speaks truly, the relations between the British Government and the Submarine Company have not been maintained on the most friendly footing, whilst those with the powers on the other side of the Channel have always been cordial. We have ourselves to blame, therefore, if the Channel Cables, fighting for their very existence, have sought safety in the good offices of a rival Power.

That our French rivals should have an influential voice in deciding this question seems to be quite overlooked in England. The cables land on the French coast as well as on the English, and the terms on which they will remain are surely matters for the French to decide. France shares with us the distinction of establishing these cables, the first experiments in submarine cable laying; and a considerable amount of French capital was embarked in the venture. We are not able to say how much is still retained in French hands; but a large proportion of the Company's stock consists of French scrip, and its French holders will naturally ask their own Government to protect their interests. Even from an English point of view, which has latterly assumed an attitude of antagonism to monopolies, the expiration of a monopoly does not involve the extinction of its business. Yet the absolute extinction of this cable business is accepted by the *Central News* and its informant as a matter of course, and the Submarine Telegraph Company as if it were as dead as Queen ANNE. Unless, however, the British POSTMASTER-GENERAL is prepared to drag up the shore ends of the Company's cables, or to put an embargo on all telegrams travelling over them, we do not exactly see how the Company can be prevented carrying on their business as before. And assuredly if the French Government were to decline to give him permission, the English POSTMASTER-GENERAL cannot land any opposition cables of his own on French soil.

We are playfully reminded in the second day's edition of the *Central News* programme that "although the Post Office declines to pay anything for the goodwill, the Submarine Telegraph Company will be able to pay its shareholders par value for their stock, as the Company has a substantial reserve fund." It happens, however, that the compulsory purchase clauses which find a place in modern legislation—generally to the suppression of all enterprise—were wholly unknown when the French concession was granted, and it is not competent for us to apply them retrospectively to a company simply because we want to get possession of its property. Not even the bribe of a "special reduced rate for Press messages" foreshadowed by the *Central News* would, we venture to think, induce the Press of this country to back up any of the high-handed measures we have just adverted to. For our part we do not suspect the Post Office of entertaining them. If it succeed in persuading the French Government on international grounds to waive its right to grant a further concession, the Post Office will be confronted by the Company alone, and the question will then arise: Are we to compete with each other, or are we to unite? That, so far as the facts at present known enable us to judge, is the simple issue. For the Company, the question is a grave one; but it is hardly less so for the British Government: and this being the case, we trust that the parties will approach each other in a conciliatory spirit. It is true that the Company have had little ground to expect that the exclusive rights they have enjoyed so long would be renewed; but, on the other hand, the British Government have had no right to assume that they would step into the expiring monopoly without paying something for it. As Englishmen, we should like to see these cables entirely in English hands; but as men of business we hope they may be acquired on terms fair and honourable to all concerned.

THE BREAKDOWN OF THE BOILERS AT THE VIENNA OPERA INSTALLATION.

The correspondents of the daily papers have given various versions of the reasons which have led to the stoppage of the Vienna Opera installation, but we have ascertained that the statement which attributes the failure to the boilers is substantially correct, the truth being that at the express wish of the local authorities the boilers were furnished by an Austrian firm. It is true that many boilers of similar type are at work in all parts of the world; but these are mostly of English manufacture. It appears that in this case both material and workmanship were of inferior quality. The following addi-

Digitized by Google

tional particulars from the *Daily Chronicle* are also substantially correct:—

"The local authorities have condemned the boilers and insisted upon their being placed under repair. The company, on the other hand, declare that this step was not at all necessary, as the boilers could have been easily replaced while under repair. The loss entailed upon them is very great, as they have to pay a penalty of 3,000 florins a night for any interruption of the lighting arrangements, and this is not the first time the penalty has been imposed, as on a former occasion they had to pay a total penalty of 32,000 florins. Pending the repair of the boilers it is probable that a temporary central station will be established, naturally at the expense of the company, which is endeavouring to obtain permission to put up the necessary boilers, provisionally, in the Schencken strasse, close to the central station."

The Times correspondent says:—

"The Opera is likely to remain closed for some days, as an official committee of inspectors decided this morning that electric lighting should no more be furnished from the existing boilers at the central station. As already reported, these boilers of Austrian make have proved quite inadequate for the work required of them. There are few theatres in Vienna, so that the closing of the Opera is sharply felt by the public; but the ultimate result of this little misfortune will probably be greater circumspection on the part of the authorities in meddling with foreign companies undertaking public works which the authorities cannot accomplish for themselves."

ELECTRICAL PUMPING PLANT AT ST. JOHN'S COLLIERY, NORMANTON.

A very interesting example of the electrical transmission of power has recently been carried out by Messrs. Immisch and Co. at St. John's Colliery, near Normanton, where a dynamo and motor are now at work raising 39 gallons of water per minute through a head of 530ft., amounting to a theoretical duty of 207,900 foot-pounds, or 6·3 horse-power. We referred briefly to this installation on the 2nd September, but we are now indebted to Messrs. Immisch for the following detailed description of the installation, together with the accompanying indicator diagrams.

Work Done.	Speed of engine.	Volts on dynamo	Av. amps. given out by dynamo.	E. H.-P. given out by dynamo.	Work done in cylinder of engine.	Loss in cables res 29 ohms, 800 yards, 19/16.
Pumps delivering 39 gallons per minute.	86	171 173·5	47·5 47·5	10·9 11	14·2	·88 h.-p.
Pumps running with the suction clack lids off and the column empty.	86	134 128 127	28 28 26	5 4·82 4·45	6·3	·305 h.-p. ·305 h.-p. ·265 h.-p.
Motor and first motion shaft only.	88 86	111 105	20 20	2·96 2·8	4·8	·156 h.-p.
Dynamo only, running on open circuit.	86	0	0	0	1·715	0

Efficiency per cent. with full load $\frac{6\cdot3}{14\cdot2} = 44\cdot4$.

A single cylinder horizontal engine was used. The bore was 14in. and the stroke 15in. The steam pressure was varied by a reducing valve according to the work required.

This engine was an old girder engine. During the test it was found that the slide valve nuts had shifted on the bottom end. The diagrams are thus defective, since the steam was admitted too late and cut off too soon on the bottom end. This must have lowered the efficiency of the engine to some extent, and of course is against the net efficiency of the system. The power required to overcome the friction of the engine and dynamo without any load was 1·715 horse-power.

Both dynamo and motor are of the well-known Immisch type, and need no detailed description.

The motor ran at a speed of about 650 revolutions per minute during the test, the pumps making 8 revolutions.

The gearing consisted of three transmissions. The first a 10in. cotton belt, the second a mortised pinion gearing into a cast-iron wheel, and the third a cast-iron pinion and a wheel on the crank shaft of the pumps. This complex system for reducing the speed of the motor was, of course, not originally designed so, but circumstances made it convenient to use gearing in this manner.

The pumps were made by Messrs. Bradley and Co., of Wakefield, to the design of Mr. Brown, the engineer at the colliery. They consisted of two separate differential pumps. Each had one 6in. ram and one 4½in. ram. They were coupled by cross heads and connecting rods to the main shafts, with the cranks at right angles.

The suction was only made by the 6in. rams, but all the rams delivered water into the column; there were thus two suctions and four deliveries per revolution of the crank shaft, the pump being equivalent to a four-throw pump with 4½in. rams.

The division of the work done by the large rams was not by any means equal. Though to casual inspection the work done throughout a revolution was constant, an ammeter in circuit with the motor showed considerable fluctuations of current at regular periods. The difference of load thus experienced was as much as 25 per cent., and caused at first some trouble by heating the armature and pole-pieces, if the average current exceeded 50 amperes.

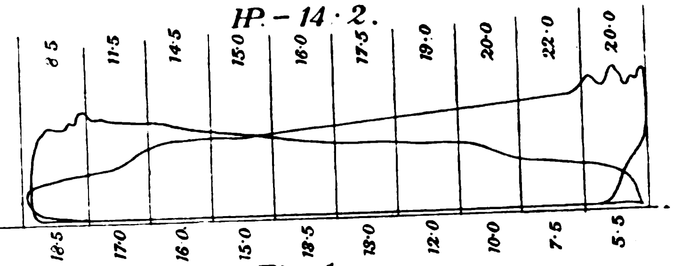

Fig 1.

Pumps delivering 39 gallons per minute.

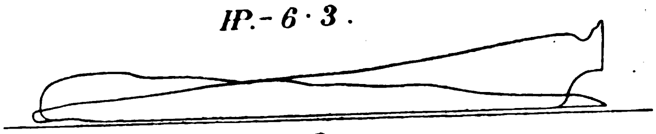

Fig 2.

Pumps Running with the Suction Clack Lids off and the Column empty.

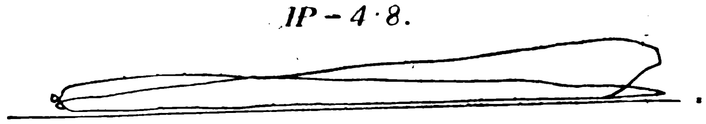

Fig 3.

Motor and first Shaft only.

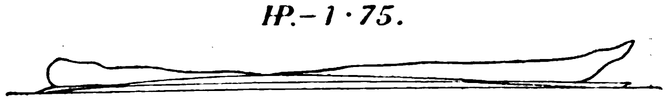

Fig 4.

Dynamo only on open circuit.

This difficulty, however, was successfully overcome. The same plant was tested under different circumstances about three weeks before these tests were made, and the conversion was then 42 per cent., with a delivery of about 42 gallons per minute through 850ft. The rise of efficiency to 44·4 per cent. is probably due to the friction of the bearing surfaces being lessened by wear, and by the shortened length of piping; but more so by the introduction of the belt transmission protecting the motor from the vibration which is inseparable from high-pressure pumping plant.

We may mention that this plant is giving great satisfaction, and that the colliery owners, Messrs. Locke and Co., have given Messrs. Immisch and Co. an order for another dynamo and motor to deliver 120 gallons per minute, through a head of 900ft. The plant is already in hand, and will shortly be delivered.

The Electric Light in Spanish Theatres.—A meeting of the Madrid Theatrical Board was to be held last week to consider the question of the installation of the electrical light, the use of which is to be made compulsory within a period of six months. It is stated that incandescent lamps are to be used to the exclusion of arc lamps, exception being made in favour of a light of the latter description for scenic effects.

THE LIEPMANN CARBON WORKS.

On Friday last, at the invitation of the directors of the Liepmann Carbon Company, a party of engineers and electricians proceeded to Millwall, and were conducted by Dr. Liepmann over the Carbon Company's Works, where the successive stages in the manufacture of arc lamp and battery carbons were carefully explained. This industry has now been carried on at Millwall for over two years, and the result of the experience gained has been to enable Dr. Liepmann to introduce some important improvements in the manufacture, in which respect the proce s carried out differs from that of other makers. The Liepmann carbons are characterised by an almost entire absence of ash, great density and uniformity of structure, and consequent high conductivity.

The crude material consists of an almost absolutely pure carbon, specially prepared for this purpose by a process of destructive distillation. This material is first passed through a disintegrator, where it is ground into an impalpable powder. After being dried and heated (during which process the powder cakes together in lumps), it passes into a mortar-mill, where it is ground together with a measured quantity of a specially prepared tar. About 60 or 70lb. of the mixed material are ground in one charge, and the process occupies about three-quarters of an hour.

The plastic material which results from this treatment is now in a condition to be moulded into the form either of rods for arc light carbons or of battery plates of any required size. For the first named purpose it is passed through the cylinders of a hydraulic press, where it is subjected to a pressure of 5½ tons on the square inch. The carbon is thus slowly squeezed through a tubular die of the required dimensions, and issues continuously in the form of a somewhat plastic rod, which travels over rollers upon a long table placed in front of the hydraulic cylinder. As soon as the advancing end of the issuing carbon reaches a certain point a number of knives descend and cut the carbon into the required lengths. An attendant immediately removes these pieces, and the operation goes forward continuously. There are two of these presses at work, one forming solid and the other cored carbons; each press is capable of turning out 10,000 feet of 11mm. carbons weekly. The cored carbons are as yet merely hollow cylinders, the soft core being afterwards inserted by a separate process.

The carbons in their present condition, although dense and heavy, are still soft, moderately plastic, and not very coherent. A 11mm. rod 1ft. in length can, for instance, be bent nearly into a circle without breaking, but with a little more strain they break straight across the grain. The next process is the packing of the carbons in iron boxes, together with carbon dust preparatory to baking in the furnaces. This is a process requiring special skill and care on the part of the workman, as a whole charge may easily be spoilt by improper treatment. It was courteously intimated that certain details of the nature of "trade secrets" are connected with this process of baking, and this portion of the operation was therefore not investigated by the visitors.

On leaving the furnace, and after cooling, the carbons are tested for conductivity. This is done by a very ingenious method, which enables an unskilled attendant to separate the carbons of too high resistance with great rapidity. The electrical portion of the apparatus is, in fact, entirely automatic, and all that the attendant is required to do is to turn a handle with one hand and feed in the carbons with the other. The carbons are thereby sorted into two divisions, and those whose resistance exceeds a certain standard are returned for further treatment, the nature of which was not disclosed. The principle of this ingenious machine is very simple. The carbon on passing into the front portion of the hopper forms a shunt to an electro-magnet. As the carbon travels onward, if it is of good conductivity it passes under a pair of brass rods or claws, and falls into a compartment below. These rods or claws are held in position by a spring which is opposed by the electro-magnet; if, then, a carbon of bad conductivity is inserted, the strength of the magnet increases, as it is now shunted with a higher resistance. The rods then rise and guide the carbon into a second compartment.

The next process is to trim and point the carbons upon an emery wheel, and unless they are required to be coppered the manufacture is now complete. The coppering is done in a frame holding about 60 carbons at a time. This is divided into four sections, each of which can be independently raised, and an attendant can be kept constantly at work filling and emptying the frame—that is to say, by the time he has gone through the four divisions, the first lot are just ready for removal.

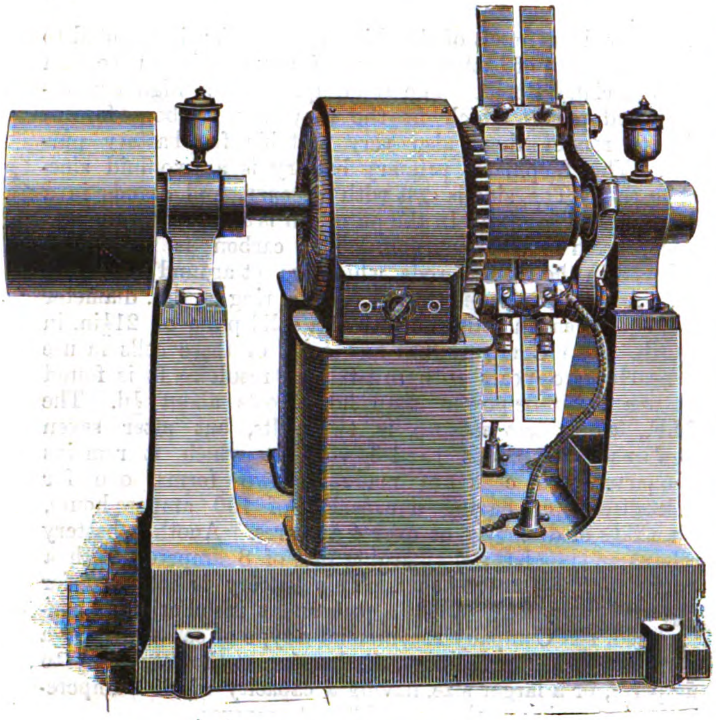
Another department of the Liepmann works is devoted to the manufacture of battery carbons of any required type, and also of Leclanché cells. The same qualities of high conductivity and purity which fit the Liepmann carbons for arc lighting render them also very suitable for battery purposes. The Liepmann primary battery is a two-fluid zinc-carbon cell. The zinc is cast with mercury, and stands in a sulphuric acid solution. In the outer cell is used a specially prepared chromic acid solution. The carbon is preferably employed in the form of rods, which are set around a collar of lead. A large surface is thus secured, a ring of 6in. diameter being equivalent in active surface to a solid plate of 21½in. in breadth. The Company has had some of these cells in use for nearly two years with satisfactory results. It is found that one 8 candle-power lamp hour costs about ½d. The E.M.F., when first set up, is two volts, but after seven hours' use this drops to 1·8 volt, at which it remains stationary. The cells are made in two forms, one for quick discharge, having a capacity of 150 ampere-hours, with a rate of discharge of over 4 amperes. Another battery of the same type has a discharging rate of 8 amperes, with a capacity of 400 ampere-hours. This battery is intended for temporary purposes. When a permanent installation is contemplated, the Company recommend a type of cell which has a capacity of 300 ampere-hours, discharging at the rate of 1½ to 2 amperes, or a larger size, having a capacity of 600 ampere-hours, discharging at the rate of 3 to 4 amperes.

THE "BLAKEY-EMMOTT" DYNAMO.

We illustrate this week a new pattern dynamo made by Messrs. Blakey, Emmott and Co., of the Northern Telegraph Works, Halifax. It is of the single magnet type, with the poles at the top. The whole magnet is in one U-shaped forging, thus avoiding in the magnetic circuit both the resistance of joints and the use of cast iron. The armature is of the modified Gramme type, and is built up of thin insulated discs of annealed iron, the whole being securely mounted on a gunmetal spider, which is keyed to the shaft, thus ensuring positive mechanical driving. The armature is wound with only one layer of wire. The commutator consists of 40 sections of specially hard drawn copper insulated with mica. There are two brushes on each side, each separately adjusted and fitted with hold-off catch. The shaft is of steel, the bearings are of best gunmetal, and are of ample length; sight feed lubricators are used, by means of which the quantity of oil delivered can be readily seen and adjusted. The pulley is wide, thus favouring steady driving. The whole machine is put together on a strong cast-iron base, which makes a very rigid foundation. The machine under notice, which is compound-wound for constant potential, is intended for an output of 60 amperes and 100 volts, the speed being 1,100 revolutions per minute. The cross sectional area of the magnet bars is 30 square inches. The total cross-sectional area of actual iron in the armature is 20 square inches. The total excitation of field-magnets at full load is 12,130 ampere-turns. The total strength of useful field is 378 lines (English measure). The density in the magnet cores is 12·6 lines per square inch, and in the armature core 18·9 lines per square inch. The length of wire on the armature is 360ft., which is at the rate of 43·2in. per volt, or at a peripheral speed of 3,000ft. per minute, at the rate of 37·3in. per volt. The total weight of copper in the machine is 95lb., and in the armature

Digitized by Google

alone 13lb. This gives an output of 63 watts per lb. of copper in the whole machine, and 461 watts per lb. of copper in armature only. The electrical efficiency at full load is over 92 per cent. The machine keeps cool after long runs, and there is a total absence of sparking at the brushes. This type of machine is now being constructed by Messrs. Blakey, Emmott and Co. in different sizes, intended for outputs varying from 10 to 1,000 lamps. We may add that the machines are mechanically well finished, and the electrical efficiency of the larger



The "Blakey-Emmott" Dynamo.

machines is still higher, an 18-unit machine giving over 95 per cent. electrical efficiency.

THE LIGHTING OF LEAMINGTON.

In our issue of October 21 we gave a description of the mechanical arrangements adopted at the Central Lighting Station at Leamington; we now proceed to the electrical details, merely reminding our readers that the dynamos are driven by cotton ropes from a counter-shaft. Power is furnished by six Robey engines, each of 200 horse-power.

The Dynamos.

The installation, it will be remembered, has been carried out by Messrs. Chamberlain and Hookham, of Birmingham, and dynamos of the Hookham type are employed. There are six machines, each having an output of 500 amperes, at 110 volts and 760 revolutions, and supplying current for 1,000 lamps of 18 candle-power. A description of this type of machine will be found in *The Electrician*, October 1, 1886. These machines have double horizontal field-magnets, shunt-wound, with drum armatures. The winding is somewhat similar to the Brown "Oerlikon" machines, the wire lying in grooves cut within the cylinder close to the surface, so that this armature presents to the field-magnets an unbroken iron surface. The armature is 25in. long by 10in. diameter, and has 18 effective turns. The electrical efficiency at full load is given as 97 per cent., and the commercial efficiency 95 per cent. Each machine weighs 72cwt., and occupies a floor space of 8ft. by 5ft.

The Mains.

The mains are laid out upon the three-wire system, and two distributing boxes in different quarters of the town are put in as sub-centres of constant potential. These are connected with the central station by feeders, and the potential is kept constant by a system of indicators with hand regulation. In fact, the Edison system is closely followed in these details. The sizes of the mains were all calculated by Dr. John Hopkinson. The conductors were supplied by Callender's Telegraph and Bitumen Company, and are laid in trenches lined with brick. The cables are laid on wooden bearers supported on slate brackets, and the trench is covered in with stone slabs. The total length of the trenches is 3,500 yards, and the distance to the farthest consumer is 1,850 yards. The total length of the main and sub-main conductors is 13½ miles, and at 65deg. F. the insulation distance has been found to be 500 megohms.

The Meter.

The Hookham meter is of the electro-motor type. The instrument is a coulomb and not a watt meter. The current to be measured passes through the armature only, the resistance of the coils being less than one-six-hundredth of an ohm. In one pattern permanent magnets are employed for the field—an arrangement which we presume contemplates the necessity for occasional re-calibration. The meter is said to register accurately for any number of lamps above three, but below that number its indications are slightly in favour of the consumer. The rate of rotation of the armature never exceeds 88 revolutions per minute. We shall be pleased to hear of the continued success of this instrument.

The total number of lamps at present hung is 1,500, of which 183 (incandescents) are in the public streets. Considerable confidence is expressed that the whole capacity of the plant, 6,000 lamps, will be taken up within six months. The price charged per Board of Trade unit is very low, varying from 4d. to 7d., or from about ¼d. to ½d. per lamp hour.

ELECTRIC LIGHTING ON STEAM YACHT "THETIS."

This handsome yacht, which has just been built for Mr. John Donaldson, of Chiswick, has been fitted with a very complete installation of electric light by Messrs. Muir, Mavor and Coulson, of Glasgow. About 100 lights are fitted throughout the ship, electric lights being used in the masthead and side-signal lamps and in the anchor lamps. The fittings in the saloon, deck houses and cabins are of a very handsome type, and the globes, which are egg-shaped, are about two-thirds obscured; the upper third being clear allows the light to strike directly on the white ceilings, which reflect the light, adding considerably to the effect. Portable hand-lamps are provided in each of the six large store and baggage rooms in the hold, at the steam steering gear, and in the engine room, for examining the accumulators, and for the bilges, &c. There is also a gangway lamp, enclosing three 50 candle-power lamps, which may be suspended from a small special davit on either side of the navigating bridge; a strong diffused light is thus thrown along the ship's side, which is a great convenience for boats leaving or coming alongside.

Another beautiful addition to the installation is a projector. Pedestals, to which the cables are brought, are fixed on either side of the bridge, and the cylinder containing the lamp and mirror may be mounted on either side as required. (When not in use it is secured on the centre line of the ship.) To extend the range of usefulness of this interesting adjunct a dispersing lens may be fixed to the front of the projector. This disperses the rays in a horizontal direction, giving a flat beam when it is desired to light a large area of quay side or beach for the use of small boats when embarking passengers, water or provisions. The wiring of the ship is divided into five circuits, controlled from the upper platform of the engine room, where the switchboard and measuring instruments are fixed. Double pole fuses are fixed on the switch board for each circuit, and from these fuses the cables are led directly to five distributing boxes in various parts of the ship. All the branch wires converge from the lamps to these boxes, and are connected to the cables through double pole fuses. The distributing box for the lamps in machinery space is fixed in the engine room, and is of cast brass, perfectly watertight; all wires in engine and boiler rooms are sheathed with lead. The advantages of such a system of centralised double pole fuses are obvious. The fuses and switches throughout are mounted on slate bases, and the cables are encased in substantial teak wood casings. In each case where a watertight bulkhead is pierced the wires are brought up to the upper deck and down again as required, no holes being allowed in bulkheads below the main deck.

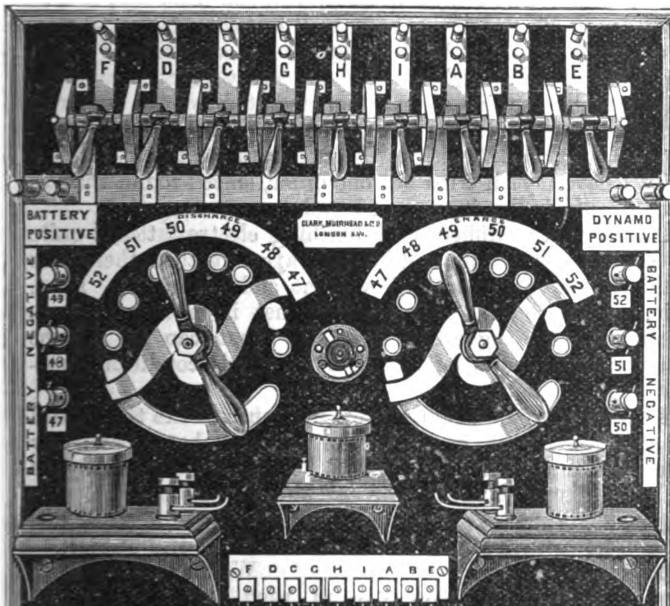
An accumulator with a capacity of 600 ampere-hours is fixed in the engine room beside the generating plant. The boxes, which are of metal alloy, are arranged in three tiers up the ship's side. They are set upon glass insulators, and each cell is separately secured in place by a system of levers and screws, completely insulated by glass insulators. The generating plant consists of a "Willans" central valve compound engine, coupled direct to a Siemens dynamo, which is wound to give 120 amperes at 65 volts as a single shunt, and at 50 volts as a compound machine at a speed of 400 revolutions per minute. The engine is fitted with a Willans governor, a sight-feed lubricator, and a tachometer. A somewhat unusual feature of the installation is a complete auxiliary condensing apparatus; this has been designed and manufactured by Messrs. Thornycroft. It consists (in addition to the copper condenser and hot well) of a small double acting vertical

Digitized by Google

engine, running at 400 revolutions per minute, driving through worm gearing a shaft to which are coupled by cranks the circulating air and feed pumps. A three-way cock is fitted in the Willans engine exhaust pipe, so that the exhaust may be directed into the main condensers, the auxiliary condenser, or the atmosphere. The feed water from the auxiliary condenser may be delivered to the main or to the auxiliary boiler. The complete plant, consisting of the dynamo and Willans engine, the condenser and circulating gear, and the storage batteries, is arranged on the starboard side of the engine room between the starting platform and the ship's side, but does not in the least encroach on the space required on the platform, while every part is easily accessible. The arrangements appear admirably adapted to the ship, and no trouble has been spared to make this one of the most perfect installations afloat.

ELECTRIC LIGHT SWITCH-BOARD, BY LATIMER CLARK, MUIRHEAD AND CO.

The adjoining figure represents the arrangement of the switch-board, supplied by Messrs. Latimer Clark, Muirhead and Co., which they specially designed for the installation at Lloyds, Barnetts, and Bosanquets Bank. The following description is furnished by the makers :—"The voltmeter is connected by one of its terminals to the connecting bar carrying the cables from the positive poles of dynamo and battery, and by the other terminal to the lever of a small switch in the centre of the board. Readings of the E.M.F., at which the installation is being supplied, are obtainable by turning this lever to right or left, connection thereby being established with the charging or discharging circuits respectively through the large six-way switches. Two ammeters are permanently affixed, giving the strength of current in the two circuits.



"The upper part of the board comprises nine main switches, corresponding to the positive cables of the nine sections into which the lamps on the premises have been divided, and on the lower edge are nine fusing bridges inserted in the negative mains.

"The Phœnix fire regulations were complied with in regard to the wiring throughout the building, and by mounting the whole of the apparatus on a solid slab of slate 3ft. square by 1¼in. thick, secured to the wall in a wooden frame. Ayrton and Perry's spring voltmeter and ammeters are employed, manufactured by Latimer Clark, Muirhead and Co."

PRIMARY BATTERIES FOR ILLUMINATING PURPOSES.

(Continued from page 19.)

The Upward Battery.

A decided departure in primary batteries was brought out in July, 1886. This was the Upward battery, in which a gas is used electrolytically instead of a liquid, thus dispensing with the use in the cells of acids and depolarising solutions. The battery consists of glazed earthenware cells divided into compartments, containing ordinary carbon plates surrounded by crushed carbon. These divisions alternate with chambers in which ordinary commercial zinc is placed in blocks. The chambers are filled with plain water and the compartments containing the carbons are permanently closed with cement. Electricity is generated by chlorine gas, which is admitted to the closed chambers, and circulates from cell to cell, giving the high electromotive force of 2·1 volts, and maintaining a constant current of electricity without the use of a depolariser or any acid or chemicals in the cells. All the attention which the battery requires is the addition of a little water about once a week, and the renewal of the zinc about every six months. The manufacture of the chlorine gas (which is non-explosive under any circumstances) is very simple. The apparatus which is seen in the illustration consists of an earthenware pan, B, containing manganese, a jar, A, for the hydrochloric acid, and some ordinary drain pipes, D, cemented together for holding the gas. Once in twenty-four hours a small supply of acid is admitted on the manganese by turning a tap for a minute or two, a gauge on the jar A marking when the required quantity has been admitted, the acid being neither seen nor handled. F is a clockwork switch. Gas is then produced, the battery working on quite automatically as long as there is gas, and the making of gas only taking place when the gasholders are empty. The presence of the gas, which is of a yellow colour, is indicated by glass globes fixed upon the holder connections. The replenishing of the acid jar depends upon its size, the ordinary jars holding sufficient for fourteen days' consumption, the manganese being exhausted in about that time. The current, when generated, is stored in the accumulators E, which provide for the lighting of the lamps, with absolute steadiness and constancy at all times. The current can also be used for driving small machines, and for other useful purposes.

The author recently inspected an installation at Messrs. Woodhouse and Rawson's, which is in use for lighting the offices. It is equal to a supply of 700 watt-hours of current, or, put in other words, is capable of driving twenty-four glow lamps of 10 candle-power each. The arrangement is slightly different from that shown in the illustration, which only occupies a space of 12ft. by 4ft. by 9ft. high. The plant at Messrs. Woodhouse and Rawson's is placed in a recess in the vaults of the building measuring only 5ft. wide by 6ft. deep and 8ft. high, the gasholders being sunk a foot into the ground, and the accumulators and switch occupying two small shelves in front of the main plant. As a matter of fact, the plant can be placed anywhere—in a cellar, shed, or on the roof—being unaffected by frost, and occupying but a small space. It will be seen that the apparatus is simple in construction. It, moreover, requires no special skill in management, and is not likely to get out of order. Its further advantages are that it works almost automatically, is noiseless, free from obnoxious fumes, and appears to give no trouble in working It is stated that the working cost was formerly equal to that of gas at 8s. per thousand ; but that it is now much less, owing to some improvements recently introduced into the generating apparatus by Mr. Upward. Dr. Oliver Lodge, of University College, Liverpool, had an Upward battery at work in his laboratory for several months, and he reported very exhaustively, and at the same time favourably, upon it. The gist of his report is that nearly all the defects of other batteries are absent from it, and he concludes by congratulating Mr. Upward upon the energy and perseverance with which he has tackled and overcome one difficulty after another, and so developed from a somewhat unpromising beginning a really practical and successful primary battery, and we here may well do the same.

The Regent Battery.

The Regent battery was brought out in August, 1886, with the object of overcoming polarisation—that is, the collection of hydrogen gas on the negative element—and local action, which is produced by irregularity in the composition of the positive element, some parts of which are more highly positive than others so that local currents are set up, thereby consuming the metal and exhausting the battery. This was a two-fluid battery, and consisted of an outer cell of porcelain, and an inner cell of porous clay, rendered highly conductive by a special process. The inventor claimed to be able to reduce the electrical resistance of the porous septum without at the same time increasing its porosity to liquids, thus limiting the diffusion whilst reducing the internal resistance. The active or positive element of the battery was an alloy, consisting principally of zinc, so treated that repeated amalgamation was obviated. The plate remained perfectly bright during consumption, and economy of working by the absence of local action was claimed for it. The other element of the battery was a carbon plate immersed in an oxidising solution, which was said to combine cheapness with constancy of action and almost complete freedom from fumes. The author has recently endeavoured to discover the whereabouts of this battery, but without success. It is noteworthy as being one of the first to be utilised for the purpose of mining lamps.

The Pollak Battery.

In October, 1886, Messrs. G. Binswanger and Co. (now the General Electric Apparatus Company) introduced a primary battery which was intended not so much to supply a constant light as for use where an immediate, convenient, and safe light is required for short periods. This was the Pollak battery, each cell of which consists of a glass jar, at the bottom of which is the zinc electrode. The other electrode is carbon, made by Mr. Pollak's process, which ensures great porosity, a large surface, and, at the same time, good conductivity. The lower part of the carbon is plated with copper, or in some cases a small piece of copper wire is suspended in the fluid and connected to the carbon. The zinc of the cells for lighting purposes is covered with sand, and the exciting solution is sal ammoniac dissolved in water. When thus charged the action of the battery is two-fold. First, a local action is set up between the carbon and copper, which causes the reduction of part of the charging fluid and pro-

Digitized by Google

duces combinations of copper. In the case of sal ammoniac, chloride of copper is produced, colouring the fluid blue and forming the depolariser of the battery. When the outer circuit is closed the action is that of a carbon, zinc, sal ammoniac battery, the nascent hydrogen reduces the copper chloride to copper, which is again tranformed into copper chloride. Thus the battery constantly forms its own depolariser, *i.e.*, it recharges itself, and therefore such a battery should be one of the most constant known. As will be readily understood, this battery depends largely on gravity, both to prevent local action on the zinc and capillary attraction; it is therefore essential that the quantity of copper solution should be regulated, and also that the cells should not be moved or shaken. By the kindness of Mr. Binswanger, the author is able to place a Pollak cell and a glow lamp upon the table, more as a matter of history than anything else, for, with a creditable frankness, Mr. Binswanger informed the author that the battery was found wanting in practical use. The E.M.F. proved to be so small and the resistance increased so considerably with a number of cells that it had to be given up. Still, as a novel and an ingenious primary battery it had its merits.

THE UNION BATTERY.

At the close of last year the Union battery was brought into public notice, and its working was shown to the author. This is not a primary battery in the strict sense of the term, although it is claimed that it is so to a certain extent. The installation which the author inspected consisted of a battery of 20 cells, which provided the current for 16 Woodhouse and Rawson glow lamps of 12 candle-power each, an excellent light being given. Each cell in this battery is contained in a wood casing measuring 11in. long by 6in. wide and 7in. deep. The whole weighs 20lb., and is said to have a capacity of 115 ampere-hours. Each cell contains six anodes and seven cathodes immersed in a solution of sulphuric acid. The negative plates are specially prepared, and are set into a very hard and durable substance, possessing great porosity and conductivity. They will not only bear transport, but can be stored dry for use at any time. The conductor is so protected as to prevent its oxidation, thus avoiding loss of capacity by the buckling of the electrodes, and the active material cannot become detached or disintegrated. The cathode is spongy lead, and the whole constitutes a feeble primary battery. The plates are therefore removed from the cells when exhausted, charged from a dynamo, and replaced for use. In these batteries there is said to be no waste of power by local action and consumption of expensive material. The *modus operandi* is to charge the plates at the works, and to deliver them to consumers, who use them until they are exhausted, and then send them to be recharged. By favour of the Union Electrical Power and Light Company the author is able to illustrate this system by a battery and glow-lamps driven from it.

(*To be continued.*)

CORRESPONDENCE.

THE TEACHING OF ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am much obliged to the reviewer of my "Electricity" for the very careful consideration that he has evidently given to my book. It is, unfortunately, very seldom that the writer of a critique gives so much attention and time to the book that he is reviewing, and still more seldom does he bring into such prominence all that he recognises as deserving commendation, while advancing almost with hesitation his adverse criticism.

I understand that it is with the *order* in which I have taken the various parts of the subject that my reviewer finds serious fault. He would, for example, begin with the voltaic circuit, arrive at the consideration of magnetic fields through the phenomena of the electric current, at permanent magnets through solenoids, and at electrostatics (perhaps) through the phenomena of the Ruhmkorff coil.

At the present moment I am myself too much used to think in my own lines to be a good judge of an order of treatment so radically different from my own; hence, I would be understood to be rather advancing reasons in favour of my order than opposing as mistaken the order suggested in the critique.

I may, perhaps, begin by saying that the whole question with me is—what is the best order for *teaching* purposes? From a physical point of view, I quite admit that the order followed in my book presents "geological faults."

Now it seems to me that if one begins with the voltaic circuit there is danger of confusing the learner by the presentation of too many new conceptions at once; for we are concerned at the same time with electric quantity, electrostatic potential-difference (from point to point along the wire), magnetic fields, and magnetic potentials, as well as other matters that I will not specify. I should, myself, feel it very difficult to know where to begin, assuming, as I do, that the learners are not only strange to the subject, but also young and devoid of much mental training.

My idea was this. First to introduce the learner to the conception of fields of force and lines of force, and also to give him some ideas of exact measurement and of a rational system of units in the comparatively simple domain of "elementary magnetic phenomena." I therefore took this part of the subject first, not because it naturally or physically came first, but because it gave a good preliminary training from the teacher's point of view.

Next came the true beginning of the subject, and I chose electrostatics for the following reason:—It seemed to me that a sound understanding of electrostatic potential was certainly to be aimed at, and that at any rate *some* knowledge of it was desirable before discussing the voltaic circuit. Now, this part of our subject can be best attacked by a study of electrostatic phenomena where we are concerned with strains and stresses only, and not with what I may call complicated dynamic phenomena also.

When once the learner has mastered separately the ideas connected with magnetic fields on the one hand, and electrostatic potential differences on the other, he is in a condition to observe intelligently the phenomena of the voltaic circuit, and there will be no need for long digressions on the principle of the galvanometer, or on electrostatic potential as involved in Ohm's law, &c.

I do not wish to take up more space with explanations as to my reasons for the order chosen; I have said enough to show that perhaps the best order in an educational book may not be that order in which there are fewest "geological faults"—not, in fact, the most natural order. But, at the same time, I recognise the fact that a teacher who spent many years in carrying out practically the line of teaching suggested by my reviewer might very possibly find out ways of overcoming what appear to me to be great difficulties. In six years' teaching of electricity I have myself tried but one order, since I found that, as far as I could judge, it answered well.

As regards the difficulty of teaching electrostatics, I quite agree with the reviewer, and have always felt that there was in this much room for improvement and alteration. Here, again, one has to consider not only what is most true, comprehensive, and suggestive, but also what can be taught clearly and without confusion to boys. This condition somewhat ties one's hands.

In closing I would again express my sense of the thoughtful and considerate way in which the reviewer has treated my attempt at a school "Electricity." Whatever may really be the best order and method for teaching purposes, I feel that any one would be a gainer were it possible for him to discuss the matter with such a careful thinker on the subject.—
Yours, &c., WALTER LARDEN.

The College, Cheltenham, Nov. 11, 1887.

PRIMARY BATTERIES FOR HOUSE LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I do not think Mr. Ross in his letter on the relative working costs of batteries and dynamos is quite as impartial as he presumably wishes to be. His reference to the South Kensington installation as instancing the loss of power between the engine cylinder and dynamo terminals is likely to mislead. The installation in question was quite exceptional in this respect, the reason being probably due to the number of lamps exposed in the open to peculiar conditions of humidity. In ordinary well-constructed installations, the efficiency of transmitting mechanism may be taken at ·8, and that of the dynamo at ·85, which gives a total efficiency of ·68, or a loss of 32 per cent. between the engine cylinder and dynamo terminals. Accepting Mr. Ross's data, the cost of coal for one available electrical horse-power will be $\frac{17s \times 12 \times 4\text{lb.}}{2240\text{lb.} \times \cdot 68} = \cdot 53\text{d.}$ per hour.

The cost of labour for small installations is no doubt a very serious item; but let us see how it works out for a user of, say, 62 lamps of 60 watts each, working on an average five

Digitized by Google

hours per day throughout the year. 62 lamps × 60 watts = 3,720 watts, or, approximately, 5 electrical horse-power.

The total number of hours will be 365 × 5 = 1,825, so that we get an annual equivalent of 1 horse-power working 9,125 hours.

The wages of an engine driver may be taken at £78 per annum = 18,720d., hence the charge on each available electrical horse-power per hour = $\frac{18720}{9125}$, or, approximately, 2d., and the total charge for coal and labour, neglecting expenditure in leads and other small items = 2 + ·53, or about 2½d. per available electrical horse-power per hour.

Mr. Ross states that the same can be obtained by primary batteries at a cost of 2d. for zinc; but he neglects to include the most important charge of all, namely, that for the oxidising solution; there is here not only the cost of the consumption of the liquid, but of the large residue remaining only partially expended, for to utilise the liquid to its ultimate exhaustion would mean a continual diminution in the intensity of the lights or a gradual reduction in their number.

Then as to the zinc, Mr. Ross's charge of 2d. per lb. is far too low and looks very like an inducement. Users of primary batteries will, in most cases, be retail customers, and I shall be much surprised if they do not find that through ordinary channels they will have to pay from 2½d. to 3½d. per lb.

Mr. Ross's consumption of zinc per electrical horse-power is also too fine. One pound of zinc consumed in sulphuric acid gives approximately 2,255,000ft.-lb., and from this has to be deducted the energy expended in overcoming internal resistance, and in setting free hydrogen from the negative plate; the latter alone when using nitric acid amounts to about 284,000ft.-lb., and with nitrate of soda and sulphuric acid, about a quarter as much again. Hence we have for a lb. of zinc (neglecting loss through internal resistance) about 1,971,000ft.-lb. of available electrical energy, which, if expended over an hour, would be something under one horse-power; but from this must be further deducted the very important and wasteful action of the oxidising solution on the zinc.

In view of the facts presented, I think it will be hard for Mr. Ross to present a clean bill of 2d. for fuel per available electrical horse-power. If we increase this figure by 100 per cent. or so, and then add on the charge for necessary labour or supervision, we shall eventually arrive at a very respectable total.—Yours, &c., N. G. THOMPSON.

4, Queen Victoria-street, Nov. 15th.

THE BENNETT PRIMARY BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue was printed a paper by Mr. Perry F. Nursey on "Primary Batteries for Illuminating Purposes," read at the Society of Engineers on November 7th. Describing the Lalande battery Mr. Nursey says, "Although the battery is the invention of M. Lalande, the credit of attempting to utilise the residual product from it is due to Mr. J. Berger Spence, head of the firm of manufacturing chemists bearing that name. And it came about in the following manner:—The manufacture of oxide of zinc is in ordinary a costly process, and Mr. Spence had for some time past been casting about for a more economical method. Amongst other things he tried electrical decomposition; and whilst engaged in his experiments in that direction he became acquainted with M. Lalande, who he found had a battery which was giving exactly the result Mr. Spence wanted." According to another paragraph in Mr. Nursey's paper, this all took place in 1884.

Now, the Lalande battery is really only a modification of the one bearing my name, the difference being the use of oxide of copper in the iron cell instead of iron or steel borings, and the result of the difference being an increase of quantity and constancy and a decrease of electromotive force, the E.M.F. of a Lalande being less than a volt, and that of a Bennett 1·38 volt. (*See* Sir William Thomson's letter on the subject to *The Electrician*, January 26th, 1884.) My battery was invented in 1881, and on February 1st, 1882 (the date of Lalande's patent being March 27th, 1882), I read a paper on the subject at the Glasgow Philosophical Society, in which special prominence was given to the recovery of zinc oxide from the exhausted solution, and the use of it in the arts, and a bottle containing zinc oxide which had been, at my request, recovered by Dr. Smith, of the North British Chemical Works, from a worked-out cell was handed round the audience. The exact words used by me were as follows:—" . . . . but it becomes even cheaper when it is considered that the chief product of its action is zinc oxide, known in the paint trade as zinc white, which is extensively used as a pigment, and as a substitute for white lead. It can easily be recovered in an approximately pure state from the used-up battery. From the cell which rang the bell for a month 1,458 grains were recovered, the zinc consumed being 1,170 grains. Some of it is on the table before you. Its price in the market ranges from 6d. to 1s. 6d. per lb., according to purity. As this is by no means a bad example, containing only a slight trace of iron, its value exceeds that of the zinc consumed." Further on, referring to the use a gentleman might make of the battery, I said, " . . . . and, after all, when the battery ceases to work he can take it to pieces and paint his house, or a part of it, with the products."

Besides being noticed in the Scotch journals, my paper was printed *in extenso* in several of the London periodicals, notably in *The Electrician*, Feb. 25 and March 4, 1882; the *Electrical Review*, Feb. 18, 1882; and in the *English Mechanic* about the same time; while copious extracts were given in others. It was likewise reprinted in America, and translations appeared in France, Germany, and Italy. All this took place early in 1882, yet in 1884 a company was formed in London to work the Lalande battery, which put forward the recovery of zinc oxide as a novel and principal feature, and in 1887 Mr. Nursey, while posing as an authority on voltaic batteries, gravely adopts the error!—Yours, &c., A. R. BENNETT.

8, Duddington-park, Portobello, N.B., Nov. 15, 1887.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

DEEP SEA SOUNDING AND SUBMARINE TELEGRAPHY.

On Thursday evening, November 10th, at a meeting of the Society of Telegraph-Engineers and Electricians, held at the Institute of Civil Engineers, Great George-street, Mr. Edward Stallibrass read a paper on "Deep Sea Sounding in Connection with Submarine Telegraphy." Sir Charles Bright, M.I.C.E., occupied the chair. Among the visitors present were:—Mr. J. Y. Buchanan, F.R.S.; Staff-Commander Creak, R.N. (Hydrographic Department); Staff-Commander Drake, R.N. (Hydrographic Department); Captain Mordovina (Naval Attaché, Russia); Mr. J. Rattray, F.R.S.E. (Dutch Museum Natural History); Staff-Commander Pearce, R.N. (Hydrographic Department); Captain Stanley, R.N. (Hydrographic Department); Captain Wharton, F.R.S. (Hydrographer, Admiralty); Captain Tizard, R.N. (H.M.S. "Triton," Chatham). The usual routine business having been transacted, the chairman remarked that the subject of the paper to be read that evening scarcely belonged to electricity, but it related to a very important point—the preparation for laying submarine telegraphs. These had been up to the present time almost entirely constructed and laid by England, and to such an extent that there was scarcely a part of the world with which he was acquainted without communication by submarine telegraph. He then went on to compare the present features of cable laying with those of past years, observing that the earlier cables had been chiefly laid in shallow water. The American Government had rendered assistance in taking soundings for the first Atlantic cable; since then progress had been made in deep sea soundings, of which they would hear many interesting particulars from Mr. Stallibrass. It might be taken for granted that the depth of sounding of 46,000ft. given by Captain Dareman and that of 50,000ft. given by an American officer were both errors. Admiral Richards in his last chart of the North Atlantic had eliminated almost every sounding beyond three thousand fathoms.

Digitized by Google

Mr. Stallibrass then read his paper, which occupied an hour and a-half in reading, and was frequently interrupted by applause. He commenced by pointing out the close connection between deep sea sounding and submarine telegraphy, and stated that the history of deep sea sounding might almost be said to date from the time of the first Atlantic cable scheme in 1858. The importance of soundings at frequent intervals over a cable route was well recognised as early as 1858; but until quite recently proper attention had not been given to this important matter. After a brief history of early sounding work, the writer touched upon surveys which had been carried out with a view to ascertaining the configuration of the ocean bed: this work having been carried out almost exclusively by Submarine Telegraph contracting companies. The surveys in 1882 of the west coasts of South and Central America and also Messrs. Siemens Bros.' surveys of the North Atlantic were dealt with. Many interesting details were given of the survey of the equatorial Atlantic from Cadiz to St. Paul de Loanda, on the West Coast of Africa. The vital importance of a thorough survey previous to laying a submarine cable was shown by the results then obtained, and some striking illustrations were given of the folly of laying a cable in water of which only rough indications of the depth had been obtained by soundings taken 20 or 30 miles apart, and Mr. Stallibrass urged that the difficulties encountered in several instances, both during the laying and repairing of submarine cables, might have been greatly lessened had a sufficient preliminary survey been carried out. Between Cadiz and Teneriffe alone, a distance of about 700 miles, 673 soundings were taken, resulting in the discovery of two banks, two coral patches, and four other shoal spots. Some of the inclines near these banks were remarkable for their steepness. On the east side of one of these the bottom falls precipitously for 450ft., and on a sounding taken by the "Dacia" during her survey of the Seine bank a precipice of 1,800ft. was found. The paper was illustrated, and a map of the mouth of the Congo was exhibited, showing a remarkable submarine gully or cañon, the contour lines of which were plotted from 202 soundings, many of these having been taken at intervals of less than one mile. In the mouth of this river a depth of no less than 1,452ft. was found. The Thames in a similar locality gives only about 40ft. The gully was distinctly traced 100 miles out at sea. Mr. Stallibrass predicted that far more attention would in future be paid to the way in which cables were laid than to details of their manufacture, which is now practically understood, and their lasting powers will no doubt be greatly increased thereby. After touching on the chemical composition of ocean deposits and their effect on the iron armour of cables, details were given of the principal machines which have been used in sounding, from the oldest form to the most recent modification of Sir William Thomson's pianoforte wire apparatus. Besides the numerous diagrams and maps, microscopes were provided showing some deep sea deposits, and specimens of many machines were exhibited. It seemed almost incredible that probably one-half of the cables now lying at the bottom of the ocean, amounting to a value represented by several millions sterling, have been placed on their ocean bed while those carrying out the work were almost totally ignorant of the bottom on which the cables were destined to lie. The only excuse for this seemed to have been the inefficiency of the sounding apparatus at the time these cables were laid—an excuse which no longer exists.

Discussion.

Mr. Buchanan said he thought the paper had called their attention to most of the things that had to be done in the course of a surveying expedition with a view to laying down deep sea cables. Perhaps its only fault was that Mr. Stallibrass had endeavoured to cover too much ground, and had in consequence disappointed them from time to time in passing from one subject to another so rapidly.

Capt. Wharton, of the Hydrographic Office, referred to the significance of the late discoveries of banks and shoals in the Atlantic. As Mr. Buchanan had pointed out, they showed how very little dependence could be placed on one sounding. A few miles in the open sea seemed exceedingly little when they were steaming about, and if they made a drawing on paper of the depth of the water they would see it did not require a great slope to produce a dangerous shoal within a few miles of a given sounding. Deep sea sounding was still in its infancy, and it really seemed as if it had taken all this time to recognise the necessity of the soundings being taken close together. He felt on his defence with regard to his predecessors in the Hydrographic office, and would remind the meeting that a certain amount of work could only be done in a certain time. The British Admiralty relied more on coast charts. Where the sounding was not continued, and where they were not conversant with the wire, they ran a chance of losing it.

Captain Tizard remarked that he had had no experience with the wire, his sounding having been done with the line. He thought the line would still have to be used for heavy instruments.

Mr. Charles Bright, jun., pointed out the importance of considering deep sea sounding as practically connected with the laying of cables rather than its previous history and utility. The question was to what extent it was warranted for our purposes? The time and expense of sounding should be considered as well as its advantages. Mr. Stallibrass, while treating of the cost of pianoforte wire, had omitted to inform the meeting of the total cost of a ship and crew necessary to do the preliminary investigations. There was no doubt that divers might even be employed with advantage in embedding a cable, but that was scarcely feasible. Whilst agreeing with Mr. Stallibrass on the importance of preliminary soundings, he (Mr. Bright) would remind the meeting of the importance of considering length of time and purse. The cable might be required before the necessary soundings could be completed, and the cost of the cable might have been too great to admit of the additional expense. The case of the "Dacia," mentioned by Mr. Stallibrass, was an instance of the chance of soundings, however close, with regard to the discovery of "banks" or "gulleys." In instancing the Lisbon-Madeira cable it must also be kept in mind that although by far the greater portion of the cables in use had been laid without such elaborate preparations as those recommended in the paper, yet they were mostly in capital working order. Before condemning pioneers for not taking more soundings, we should consider the improvements which have since taken place, and also the greater confidence of the modern public in such undertakings, and thus the greater ease in obtaining money for them. With regard to Mr. Stallibrass's rule about avoiding shallow water in laying a cable, it must also be remembered that a depth of more than 500 fathoms should be avoided where possible in consideration of "recovery work," In conducting chemical analysis of the parts and surroundings of the cable care should be taken to test the specimen before a lapse of time had allowed it to alter its state. An intimate acquaintance with the nature of the bottom was certainly quite as important as a knowledge of its configuration. He (Mr. Bright) presumed that amongst the recent improvements in sounding appliances those described were the ones which the author had had an opportunity of becoming acquainted with, as doubtless there are several others besides those mentioned in the paper.

Mr. Stallibrass, in reply, regretted giving offence to Captain Wharton. He himself rather found fault with the Government than with the Navy. The Hydrographic office dealt chiefly with shoal soundings. He thanked Mr. Buchanan for his kind remarks and the meeting for the vote of thanks, which was very gratifying to him.

SIR F. ABEL ON ELECTRIC SAFETY LAMPS.

At a meeting of the Institution of Civil Engineers, held on Thursday last, Mr. George B. Bruce, President, in the chair, Sir Frederick Abel, C.B., read the second part of his paper on "Accidents in Coal Mines." After describing the earlier systems the author turned to the question of electrical illumination:—

The late Commission had had the matter in view, and although it was only able to describe achievements which could scarcely be considered much more than the germs of the future utilisation of electricity in these directions, yet it was evident that the electric light had an important future before it in mines. Its application to the illumination of the pit-bottom and the immediately adjacent portions of the mine roads obviously presented no practical difficulty, while even this limited utilisation of the light, combined with its employment at the surface and in the buildings attached to a colliery, appeared likely to secure advantages in regard to efficiency of illumination, convenience, and comparative safety. Experiments were carried out at various collieries, at some of which installations of the electric light were provided and are still in use, both on surface and underground. The impossibility of guarding against injury or fracture of such light insulated wires as could alone be applied for connecting movable lamps, for use at the working places, with main conductors leading to the dynamo-machine at the surface, soon rendered it evident that the success in providing the miner with a safe and efficient electric light could only be attained by the production of a perfectly self-contained lamp, not too heavy or bulky to preclude its being carried about underground, and capable of maintaining a supply

Digitized by Google

of light equal to that furnished by efficient safety-lamps during the entire period of a working shift. When Mr. Ellis Lever offered a prize, in 1883, for the best safety lamp, two or three attempts at self-contained electric lamps were brought forward, but they could not be said to have afforded any encouragement to the hope that some practical success in this direction was imminent. The subject was, however, attacked by Mr. J. Wilson Swan, and before the Royal Commission concluded its labours Mr. Swan submitted a secondary-battery lamp of sufficiently small and suitable dimensions to be called really portable, though considerably heavier than was desirable. Fitted with a glow-lamp of suitable resistance, it gave a light which was maintained for several hours at between two and three candle-power, and furnished a light of about 1½ candle-power at the expiration of 11 hours. Since then Mr. Swan has made further improvements in this lamp, which weighs now only about 7lb. Thirty of them, supplied by the Edison-Swan Electric Light Company, have been in use at the Risca Colliery for three months, having been employed in connection with every variety of underground work. When brought to the surface at the end of a shift they are recharged with the aid of a simple charging table in connection with the dynamo of the general installation. The London and South-Western Coal Company, the Abercarn Steam Coal Company, and the National Steam Coal Company have recently decided to use these lamps in their collieries, and 3,000 will shortly be supplied for that purpose. Mr. Swan has endeavoured to make a modification of this lamp for inspecting purposes in which a gas-indicator forms part of the lamp, and of which a practical trial is shortly to be made. Mr. James Pitkin has constructed a portable and efficient variety of secondary battery, and has made a near approach towards the production of a good miners' lamp. The results which he now attains in regard to light furnished and maintenance of the light are fully equal to those obtained with the Swan lamp, and the weight is only between 5lb. and 6lb. Several attempts had been made to produce primary batteries in a portable form, of sufficient power to maintain a practically useful light for the purposes of the miner. One of the first to attain somewhat promising results in this direction was Mr. Trouvé, though the maintenance of power of the battery used by him was insufficient to serve any useful purpose underground. Mr. T. Coad submitted a primary-battery lamp which appeared to afford some promise of success, though neither the maintenance of power nor the dimensions of the battery constituted an approach to the fulfilment of practical exigencies. Mr. Schanschieff has constructed a small sulphate of mercury battery which has furnished, in regard to maintenance of power, more promising results than those attained by the batteries used by Trouvé and Coad. Early last year the author had submitted to him by Mr. Blumberg some experimental lamps in which the source of electricity consisted of a combination of small cells of Skrivanow's modification of de la Rue's battery. The elements are zinc and silver foil coated with chloride of silver, the exciting liquid being a solution of caustic potash. The re-charging of small primary batteries for miners' lamps is a more troublesome operation than the restoration of power of the secondary-battery lamps. On the other hand, the employment of the latter necessitates the provision of a generator. The great advantages secured, however, in connection with the necessities of a colliery by the provision of an electric light installation for general purposes, and for the efficient illumination of the pit-bottom and adjacent roadways render their extensive adoption very probable. There are now most substantial grounds for the confident belief that the problem of the successful and thoroughly safe application of electric light in connection with every class of underground work is in course of speedy and complete practical solution.

PHYSICAL SOCIETY—November 12.

Prof. W. E. Ayrton, F.R.S., Vice-President, in the chair.

Lieut. Bacon, R.N., was elected a member of the society.

Owing to the illness of Dr. Shettle, the paper announced to be read by him was postponed.

The following communication was read :—

On a Geometrical Method of Determining the Conditions of Maximum Efficiency in Transmission of Power by Alternating Currents. By Mr. T. H. Blakesley, M.A.

In this paper the author confines himself to the consideration of a simple circuit containing generating, conveying and recipient parts, in which the E.M.F. follows the law of sines. The maximum E.M.F. of both machines are supposed known together with the resistance and coefficient of self-induction of the complete circuit. The variable on which the efficiency of transmission depends is the difference of phase of generator and receiver. A geometrical construction is given by which the phase which gives maximum efficiency can be determined.

Mr. Kapp thought the construction would not apply where the receiver does mechanical work, owing to the E.M.F. not being a true sine function of the time. He also mentioned an experiment performed on a motor driven successively by alternating and direct currents, in which the *apparent* power ($\sqrt{e^2}\sqrt{c^2}$) supplied by alternating currents was about five times that required when direct currents were used, the motor giving out the same power in the two cases. From this he inferred that the ratio of power to weight is much greater for a direct than for an alternating current motor. This he considered a serious drawback to the use of alternate currents for transmitting power.

After some remarks by Prof. Ayrton and Prof. S. P. Thompson, Mr. Blakesley said that by placing a condenser between the terminals of the recipient machine a greater current could be passed through the receiver than that in the generator and line.

LEGAL INTELLIGENCE.

The Western Counties Telephone Company v. Harding.

In this case, the company, for whom Mr. Lapthorne appeared, sued the defendant, a builder, of Southsea, for whom Mr. Feltham appeared, for £11, being one year's rental of a telephone from the 1st of March last, under an agreement entered into between the plaintiff and defendant, and dated the 31st of December, 1886.

There was no question as to the use of the telephone, but the defence was that the wire was laid on to the defendant's premises for the benefit of the company, in order that he might be communicated with on the subject of repairs. There was a counter claim of £5 odd for breach of agreement.

Eventually His Honour gave judgment for the plaintiff for £5. 6s. 8d.

The Sanitas Company (Limited) v. The G. Condy's Sanitants Company and the Condisanitas Company.

This action was tried in the High Court of Justice on the 27th ult. before Mr. Justice Kekewich.

The plaintiffs (who are the well-known manufacturers of Sanitas compounds so largely used at telegraph stations and on board ship) claimed that the title of the defendant company constituted an infringement of their registered trade mark.

This view was upheld by Mr. Justice Kekewich, who remarked that he had not the slightest hesitation in granting the injunction.

Judgment accordingly.

COMPANIES' MEETINGS.

West India and Panama Telegraph Company (Limited).

The twenty-first ordinary general meeting of the members of the West India and Panama Telegraph Company (Limited) was held at Winchester House, 50, Old Broad-street, on Wednesday last, Mr. C. W. Earle in the chair. Mr. R. T. BROWN, secretary, read the notice calling the meeting and the minutes of the last meeting, which were confirmed.

The CHAIRMAN: Gentlemen, I presume you will take the report as read. [Yes.] Well, gentlemen, it refers to a period that certainly has not been the least prosperous that we have had to submit to you, but it has been marked by some causes of very considerable anxiety to us in the administration of your affairs arising from causes outside the regular business of the Company. I allude, in the first instance, to the long-continued depression under which the West Indian sugar trade has suffered. This depression affects us indirectly, because it contracts the traffic, and it also induces the Colonies to pull the strings of their purse in the matter of subsidies a little tighter than they would if we were in more prosperous times. Those who are more particularly interested in the sugar industry, which is the great staple of the West Indies, are aware of the extraordinary fall in the price of sugar—a fall of about 50 per cent.—and the action of the bounties that are paid by foreign Governments on the export of manufactured sugar from their countries (hear, hear). These bounties amount, I believe, in the aggregate to about £7,000,000 a year, and the effect of this is that the manufacturer of the beet sugar in France, Germany, and almost all of the Continental countries can place it upon this market at a price which is below what it would cost to produce it if it were not for the bounties. The result, of course, is very damaging to the West Indian interest. I may add that after many suggestions a sugar conference has been convened on the subject of those bounties, and is about to be held in London on the 24th of this month, and at it I hope something may be settled to modify the effect of those arrangements of foreign countries, which are so detrimental to West Indian interests. I may state that at this moment there is a little rise in the price, probably due to the shortness of the beet-root crop on the Continent. Another cause of anxiety to us during the half year was the proposal that the French Government should guarantee £40,000 for a cable that was to compete with your traffic to the islands of Martinique and Guadeloupe. The Bill was presented to the French Chamber by the Minister of Posts and Telegraphs, with all the power that he could bring to bear upon it. The promoters of this line—this scheme—gave to the Minister the most extravagant returns as to the profits that would be derived from this business, and it fell upon us to supply to the members of the Chamber that were inclined to oppose this scheme very full statistics of the actual profit probable. The subject was debated at great length in the French Chamber, where very great influence was brought to bear upon the patriotic feelings of the French members. They were told that the English were deriving enormous profits from this business; that the perfidious Briton monopolised the telegraphic communication of the world; that France ought to have her share, and should slip in and take this, at any rate, as a beginning. Well, gentlemen, the French Chamber did not see their way to what was suggested, and referred the matter to the Budget Committee, and they went into the subject (which I need not take up your time to listen to), and eventually the proposal was rejected. The Ministry suddenly fell, and I hope we shall not hear any more of it (cheers). Still, it was an anxious time, and we had a great deal to do in communicating with our agent in Paris, and endeavouring to show that no good would come of it, and what a losing business it would be. We have the satisfactory position to-day of being able to report the repair of that very important link of our cable lying between Jamaica and Porto Rico. The history of that cable has been an eventful one. When we took office in 1874 it was inoperative, and we had no ship wherewith to undertake repairs. It was some time before we got one out with cable on board, and then there were breaks in other cables which had to be attended to. In 1885 that cable was repaired, and it worked for a year. It then failed in a depth of 2,400 fathoms, or about three miles deep of water. It was found that we could not lift it at so great a depth, and we had to go a considerable distance on each side of the break into shallower ground to get hold of the cable and to relay it in nearer the coast of San Domingo and in shallower water, so as to avoid the pitfall into which the cable had been laid in the first instance. We found that the ship had to go for some other repairs, and the cable stock running low we had to bring her home for a fresh supply of cable. On her return to the West Indies in the current half year she entirely completed the repair of that cable. This has been a very expensive business from first to last, and we shall take care that the Colonies know it. The total cost, if we charge the ship's expenses in these different operations, is £50,000, and we have laid in about 439 knots of new cable, which, as the whole cable is only about 700 miles long, makes practically two-thirds of it a new one. This cable is of course a matter of much importance to us, as those islands of the Antilles ought not to be dependent upon one cable. We had hoped that in the report which we laid before you to-day we should for the first time have been able to state that every cable of the Company's system was working, but while the report was in the press the information came of a failure of the Colon cable. It appears that in one of those terrific storms that beat on the Isthmus of Panama, the cable parted about 36 knots from the coast. Our ship is on the spot, and as the break is not in very deep water we expect any moment to hear that the cable has been put through. With regard to the accounts that we lay before you to-day, I do not think that they call for any special remark. I shall be very glad to answer any questions, but they follow very much the same lines that they usually do, and there is no point upon which I can see you will expect me to make any remarks to you. I have received two letters from shareholders suggesting to the Board that something should be done to the ordinary shareholders (hear, hear). We do all we can for the ordinary shareholders in our power ("No, no"). The suggestion that has been made in those letters is practically the raising of a debenture stock in order to satisfy the claims—the prior claims—of the preference shareholders. Well, gentlemen, I am informed that such a course would be distinctly illegal, *ultra vires*, and liable to cause us to be served with an injunction—("No")—and that if we (the Directors) were to do such a thing, we ourselves would be held personally responsible, and liable to any damages that might be laid in claims against us. I therefore think that that scheme—that proposal—is an impossible one. Another proposal is that we should take the reserve fund to pay off these dividends. Now, gentlemen, that the Board is determined not to do. The reserve fund is the key-stone of the whole concern. I showed you just now how, for one cable alone, you may have to dip into it from first to last to the extent of about £50,000. We have 4,000 miles of cable, some of which has been 17 years under water, and therefore I do

Digitized by Google

not think the amount of the reserve too much as a security for the whole of the enterprise of the Company, and I therefore, myself, will not be a party to dipping into the reserve fund in order to pay dividends that have not been earned. Upon this point, to put myself quite right from a legal point of view, I requested our solicitors to furnish me with their views, after having read the letters to see what the question was, and this is what they say about it:—"Letters have been received by the Directors and have appeared in the press urging that some action should be taken with a view to improving the position of the ordinary shares with respect to dividend (hear, hear). It has been suggested that the arrears of accumulated interest on the preference shares should be capitalised, and that fully paid shares should be issued to the preference shareholders in extinguishment of their right to arrears of dividend. The Directors are advised that such a scheme would be illegal. There does not seem to be any way of altering the relative positions of the different classes of shares of the Company's capital without either obtaining a special Act of Parliament or getting the consent of every individual shareholder for the reorganisation of the capital. The Directors have no evidence that either of these courses would be acceptable to the shareholders as a body ('yes, yes'), and until such evidence is forthcoming they cannot take any step in the matter." That is what the solicitors—Messrs. Bircham and Co.—have written upon the subject. Now, gentlemen, I come to another class of letter—that which Mr. Morten is writing to the public press. They say "if you have a bad case always abuse your opponent's attorney," but I would like to know what sort of case it is that leads a man to abuse his own attorney, as Mr. Morten has been doing in the public press. You all, as men of business, know how far such a line of conduct as he has been pursuing weakens and damages your Directors in any negotiations that they have to carry on. Here we are held up as grasping—I was going to say rascals—because we take the fees that have been arranged and settled by the Articles of Association; because we take those fees—and I may state here that unless I do have my fees I will not sit here, and I do not suppose anybody else will—we are held up to opprobrium in the public press. Mr. Morten knows nothing about our business, nothing of the negotiations that have to be carried on with the West Indies, nothing of our relations with the Colonial Office, and there is nothing can be more damaging to us than he in his small way can be by the abuse he puts in the papers about us. If Mr. Morten or any other shareholder thinks he can do better with another Board, let them take steps to get a new Board. They can get the Articles of Association changed, and they can get the Directors changed, but I must most strongly deprecate the action taken by Mr. Morton in publishing what he does in the public press (cheers). Gentlemen, I beg now to move:—"That the Directors' report and accounts to the 30th June, 1887, be received and adopted, and that, as recommended by the Board, the payment of 9s. per share on account of arrears of dividend on the first preference shares be and the same is hereby declared."

Mr. W. Ford seconded the resolution.

Mr. William Abbott said that it might not be known to shareholders who had lately come into the Company that it was a reorganisation of a very bad business. He had had a hand in the reorganisation, and had helped to carry it out successfully and place the present Board in office, and the question of fees was at the time made a distinct compact with the Directors. He (Mr. Abbott) tried at the time, assisted by some of the largest shareholders in the Company, to place upon that Board the most successful men in telegraphy, and had succeeded. Mr. Ford was able to advise them legally, and Mr. Holmes had charge of the shipping interest. He did not think that they could possibly get a better Board than they now possessed (hear, hear). They had evolved a system out of chaos, and built up a reserve fund of £125,000, and, excepting for one block still in the way, which he would shortly allude to in fuller detail, they might be said to have turned the corner, and rather more than turned it (hear, hear). The Chairman's speech had not been very cheering; but, then, he never did give a very optimist view of things (laughter). It was a matter of considerable satisfaction that the French Company had come to nothing. The French wanted a share in the profits of telegraphy; he wished to the Lord that they had a share of the losses that had been made by the Panama Company. What was wanted in the Company was that something better should be done for the ordinary shareholders (hear). The letter of their solicitor had made him very raw. He did not wish to approach the Board in any combative or antagonistic spirit, but he had a scheme to propose, and if Mr. Solicitor chose to say that it could not be done he would assure him that they were determined to do it in spite of their solicitor (hear, hear), and he could assure the shareholders that in the person of Mr. Ford they would possess, on the Directors' side of the Board, a very strong advocate. When he and Mr. Ford worked together for the benefit of the Company, some fourteen years ago, they never let the word "impossible" enter into their vocabulary, and they were not going to do so now (hear, hear). The ordinary shareholder was a patient animal, and had not had a smell of a dividend ever since he subscribed his money. The scheme that he (Mr. Abbott) had to propose on behalf of himself and his friends was a scheme that he was confident would work, and that scheme was a scheme for the reconstruction of the capital of the Company. In order to place the financial position of the Company on a more satisfactory footing it was proposed to cancel the £38,019. 6s., dividends overdue on the first preference stock, by an issue of £38,019. 6s. first preference capital, equal to £1. 2s. per share. It was proposed to cancel the second preference capital (£46,690) and the accrued dividends, and to issue first preference shares in the proportion of 75 per cent., or £7. 10s. per share, in exchange for each £10 second preference share, and the dividends overdue thereon. The reconstructed capital account would then stand as follows:—First preference capital £418,666. 16s., and ordinary capital £883,210, making a total of £1,301,876, being a decrease on the present capital and dividends overdue of £32,683. The advantages of the scheme were briefly that the first preference shareholders would receive per share an additional capital of £1. 2s. The present shares are quoted £9. 5s. ex div. Valuing the reconstructed capital at £9 per £10 share (to be within the mark), £11. 2s. capital would be worth £10, showing an immediate increase in value per share of 15s. On the basis of the dividends paid for the past half year, it would take over seven years to liquidate the amount now overdue on the first preference capital. With regard to the second preference shares, the price of these shares was nominally £6. In place of the present £10 share and the accumulated dividend of £4 per share, holders would receive £7. 10s. first preference capital, which at £9 per £10 share would be worth £6. 15s., showing an immediate increase in value per share of 15s. No distribution had been made on the second preference capital for the past seven years and a-half, and as the Company had during the past twelve months paid only one excess dividend of 3s. per share to the first preference, and there still remained a sum of 22s. per share overdue, it followed on this basis that the holders of second preference shares would not receive any dividend for the next seven years until the arrears on the first preference were liquidated. By the scheme proposed each £10 second preference share would be exchanged for a freely marketable security earning a dividend of 9s. per annum. As to the ordinary shares, these would be immediately brought within range of a dividend. The Company had for the past year, after placing £6,000 to reserve (now amounting to £125,903) and providing for exceptionally heavy expenses in repairs to cables, paid in dividends on first preference capital, £25,922. 5s. The proposed 6 per cent. first preference capital would require £25,120 per annum, leaving as surplus £802. 5s. Any dividend paid on the ordinary capital would, of course, materially improve the price of the preference shares, and the prospect of such a distribution was by no means remote, as the traffic for the past four months showed an increase of £2,035, or 12 per cent. on the gross receipts. Such a scheme, he thought it would be conceded, was in the interest of all classes of holders (hear, hear). The debenture holders would not object to it (no). The first preference shareholders would not object to it (no), for their arrears would be capitalised by a payment in stock which they could take into the market and turn into sovereigns, and the second preference could not object to it (no), but yet as regarded the second preference he had been told since he came into the room that those shareholders were not treated liberally enough. Well, that could be a matter for discussion. He and his friends were now quite prepared to meet the Board in a friendly conference—not a committee, he hated committees—and to see what they could do to round off rough corners and make things fit, and arrive at something which the Directors could confidently recommend to the whole body of shareholders. To do the whole of what he had laid out in his scheme would only require an increase to their capital of £26,000, and they would be enabled to wipe off £59,000 of arrears. Their reserve fund now was 30 per cent. of the preference capital. He thought that if the Directors could only see their way to the adoption of this scheme that it would effectually end the constantly recurring disappointment of shareholders and their complaints, who, wanting a Jonah, pitched on the small matter of the Directors' fees. The day after the scheme was adopted and carried out there would be a considerable increase in the value of the securities of the Company in the market. So far in their time of probation—the past fourteen years—the Board had done wonderfully well. No one could have done better. Himself and the friends who he represented were well satisfied with the work that they had done, and they now asked them to carry out the scheme to be placed before them (loud applause).

Mr. Morten highly approved of the scheme of Mr. Abbott. It was a good workable scheme, and if it only gave the second preference a little fairer treatment, he (as perhaps the largest shareholder in the Company) would be glad to give it his approval and support. He thought that the Directors had during the past seven years and a-half taken a too pessimistic view of the affairs of the Company, and on that head he had prepared an amendment; but as he did not desire to be in any way hostile to the Board, but to support anything that was of advantage to the general body of shareholders, he would simply content himself with reading the amendment at the end of his speech, and handing it in without proposing it. The result of the gloomy view taken by the Board was shown in the low price of the shares of the Company in the market. He was prepared to purchase any of the second preference shares at £6 each. He offered that challenge to them. As regarded the remarks of the Chairman on what he (Mr. Morten) wrote to the papers, he was not ashamed of what he wrote; he always put his name and address to what he wrote, so that there might be no mistake about it. He was not one to stab in the dark; he stood up and used his fists like an Englishman. Mr. Abbott's scheme was, he might again state—and he held the Articles of Association in his hand—a workable one, and one that deserved support if the second preference shareholders were only a little better treated.

Mr. Newton said that the law was just the same now as it was when they capitalised the dividends for the Company on a former occasion, and——

Mr. W. Andrews, interrupting, said that it must be borne in mind by Mr. Newton that on that occasion the old company was wound up and the shareholders of the old company received as their capitalised dividends shares in the new Company.

Mr. Newton said that he thought the scheme of Mr. Abbott a good one, and if carried out might put an end to the constant haggling about Directors' fees. He believed it could be carried out. He had assisted in a much more difficult operation in another company, where they had induced the preference shareholders to give up their preferential rights altogether in order that the ordinary shareholders might get a dividend, and the result was that the capital value doubled in three years. He liked to hold preference shares when ordinary shareholders got a dividend they

Digitized by Google

were then of value, but it was doubtful in many instances whether a preference share was of much value unless the ordinary shareholders got a dividend. He thought that the manifestation expressed by that meeting showed a unanimous feeling of approval of the scheme of Mr. Abbott (cheers).

Mr. A. BAKER endorsed the scheme of Mr. Abbott, and thought that its great recommendation was the small amount of £26,000 only he required to carry it into effect.

Mr. ABBOTT said Article A of the Articles of Association gave power for an extraordinary meeting of the Company to increase the original capital of the Company by the issue of new shares to such amount as might be deemed expedient, and, therefore, if he understood the English language, it only required an extraordinary meeting to carry this into effect, and it might all be done before the end of the year. He did not think that the Chairman or the Directors objected to it.

The SOLICITOR said he wished to put himself right as to the letter he had written, and he wished to state that in the matter submitted to him he would stand or fall by what he had written; but if they obtained the consent of the whole body of shareholders or got a special Act of Parliament, then they could do what they liked. That letter was not written with any hostile feeling to shareholders (hear, hear).

Mr. GRIFFITH thought that Mr. W. Abbott's scheme was a very statesmanlike one, but they had not all the shareholders in that room—perhaps there were 150, and it would be a matter of some difficulty to get all the shareholders to assent ("No, no," and a voice, "We can try.")

Mr. ABBOTT said he believed if a form of assent was sent round they would not get a single refusal to sign it.

The Rev. Mr. GREAVES feared a circular would not be of much use; some would sign and some take no notice of it. He cited the case of the East London Railway Company, in which he was interested, and stated that the way in which a similar arrangement was carried out was by meetings of holders of the various classes of securities, and a quiet and business-like discussion over the affairs. He approved the scheme.

Mr. ABBOTT thought that they could not expect the Directors to decide as to the merits of the scheme offhand; he confessed that he had rather sprung it upon them, and he thought that it might be left to the Directors to discuss and go thoroughly into the matter in the board room, and then see whether it was not just the scheme that—with perhaps a few modifications—they could lay before the shareholders (hear, hear).

The CHAIRMAN confessed that it was quite impossible for him to give an absolutely definite answer now. He might speak for his Board, and say that as far as he could see at the moment the scheme had their approval (the Board: Hear, hear), and they would promise at once to give it their utmost attention.

Mr. ABBOTT expressed his gratification, and said that he knew that Mr. Ford would not allow himself to be beaten if it were possible (and he knew it was) to carry the matter out.

Mr. FORD said that if a thing was in the interest of the shareholders, the Directors were always ready to act within their powers, and if they did not possess the necessary powers then they were ready to seek them (cheers).

Mr. NEWTON asked whether the Chairman would promise to call a meeting within a month or two months, and lay before the shareholders the result of the deliberations of the Board (hear, hear).

Mr. FORD said that the matter would of course have their immediate attention.

Mr. MORTEN hoped they would try and do a little better for the second preference.

Mr. FORD said that that, in common with other matters, would receive due consideration.

Mr. NEWTON asked the amount of capital requisite to call an extraordinary meeting. The feeling was in favour of a meeting, and he thought that the Chairman ought to say they would call one.

Mr. QUILTER thought that the meeting was unanimously in favour of the scheme, and as far as he could see it was a good one. Would the Chairman pledge himself to carry it out? The shareholders would leave the room more pleased if they had that assurance.

The CHAIRMAN said he would pledge himself to consider it at once (cheers).

Mr. FORD said the amount of capital that could call a meeting was one-tenth of the whole.

Mr. NEWTON thought that perhaps it would be as well if they passed a resolution that day recommending this scheme to the Directors.

Mr. ABBOTT said that the Board had met the shareholders so fairly that day that he did not think that it was right to press them too hard (hear, hear). Let the shareholders leave it to them, with the knowledge that they would act at once (hear, hear).

The CHAIRMAN then formally put the resolution for the adoption of the report and declaration of the dividend to the meeting, which was carried *nem. con.*

On the motion of Mr. VEARS, seconded by Mr. HOWARD, a cordial vote of thanks was accorded to the Chairman and Directors; and the CHAIRMAN having briefly responded the proceedings terminated.

Rochester and District Electric Lighting Company.

The first general meeting of the shareholders of this Company was held on Tuesday night at Chatham, when it was decided that, notwithstanding the very limited support which had been accorded the promoters, operations should be commenced as speedily as possible, and an endeavour be made not only to supply Chatham and Rochester with electric light, but to go as far as Maidstone and Gravesend. The number of shares applied for is up to the present 667, and of these 446 have been taken up by the Directors. The lack of support on the part of the general public has caused the Directors to hesitate before incurring any financial liability; but they have agreed to subscribe any further capital which may be necessary, and, as a preliminary step, have signified their intention to pay up at once in full the shares already taken. They are confident of being able to supply the electric light at a rate corresponding to 3s. per thousand, and, taking all circumstances into consideration, they believe this price will in the end be much cheaper than gas, which is sold in the district at 2s. 6d. per thousand. It has not yet been definitely decided what system to adopt, but negotiations are taking place for the supply of engines, boilers and dynamos. A large number of people in the neighbourhood have expressed their desire to have the electric light.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended the 11th inst. amounted to £4,609.

OPPERMANN ELECTRIC LIGHTING AND MANUFACTURING COMPANY (LIMITED).—The principal in the formation of this Company, which was noticed at page 22 of our issue of 11th November, appears to be the same Carl T. J. Oppermann who was a bankrupt in November, 1885, and who, on being examined before the Registrar, stated that he had since his bankruptcy been a salaried servant to his brother, Lawrence Oppermann, who was then a minor. In the short period since his discharge he appears from the agreements made in this new Company to have acquired the business of this brother, a minor. This is curious, especially as the creditors under the bankruptcy have not yet received one farthing from the estate, nor will there be any appreciable sum for distribution.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts for the week ended November 11th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,651.

TERMINATION OF AGREEMENT.—We understand that the agreement between the Telephone Construction and Maintenance Company (Limited), of 109, Farringdon-road, London, E.C., and Mr. George Allanson Mason (late of the American Telephone Company) is about to be terminated.

PERSONAL.—We are informed that Mr. René Upward, until recently the head electrician to the Woodhouse and Rawson Manufacturing Company, has resigned his appointment.

REMOVAL NOTICE.—Messrs. E. L. Berry and Co. inform us that they have removed to more convenient premises, at 8, Wardour-street, London, W.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 497.—Vol. XX. FRIDAY, NOVEMBER 25, 1887. Price 4d.

NOTES.

It is interesting to note that as long ago as January, 1878, the possibility of using a condenser for increasing the output of an alternating dynamo was distinctly foreshadowed by Mr. Higgins (now of the Exchange Telegraph Company). In the course of a discussion at the Institute of Civil Engineers on a paper by Messrs. Higgs and Brittle, entitled "On some Recent Improvements in Dynamo-Electric Apparatus," Mr. Higgins made the following observations:—"But the power of the Alliance machine might be increased considerably, without adding to its bulk, by interposing in the exterior circuit a condenser of sufficient capacity. The discharge stored up in the condenser would pass back through the bobbins of the generator upon the fall and reversal of potential in the circuit, thus adding, without extra cost of machinery, to the quantity of electricity which the machine was capable of producing." It is needless to add that Mr. Higgins' suggestion is a perfectly valid one, and it probably would not have remained so long in abeyance but for the lack of a practical commercial condenser of large capacity.

The paper referred to in the above Note was, we have every reason to believe, well abreast of the science (and practice) of the times; but as an illustration of the enormous strides which have been made during the present decade, especially in the matter of "light effects," we may be allowed to quote the following extract:—

"The Best Use of Two Machines to Produce One Light.—From experiments made with the Gramme machine it has been found that, by coupling two machines in what is electrically known as parallel circuits, light effects are produced exceeding the sum of the light effects separately given by each machine."

This remark is followed by a table of experimental data.

The paper on Dr. Bernardo's system of electric welding by the carbon pencil, which will be found in another column (translated from our contemporary the *Elektrotechnische Zeitschrift*), seems to give promise of a most important future for this branch of the art. It would be rash at the present moment to offer any opinion as to whether this system or that devised by Prof. Elihu Thompson will ultimately prove to be the most advantageous. Probably each method has its own field. The transformer method has a distinct superiority in the fact that the heavy current is confined to a very short circuit, while with Dr. Bernardo's arrangement this is not the case, and the employment of a large number of accumulators, though clearly not an essential feature of the system, adds largely to its cost, and must lower its commercial efficiency. On the other hand, the employment of a continuous instead of an alternating current has evidently a great advantage in keeping the metal entirely free from oxidation. This is effected by making the metal take the place of the negative electrode. Another point in favour of the arc method arises from the fact that it is impossible in some cases to use the transformer method with its fixed electrodes in cases where tubes, or complete rings (such as boilers, &c.), are to be welded, inasmuch as the joint is short-circuited by the other side of the tube.

Since making our translation of the article referred to in the above note, we have received some direct information from Paris, where experiments of this nature have been for some time in progress at the Northern Railway Works at La Chapelle. We are sorry to learn that at present the results are not entirely satisfactory. Our correspondent writes:—"The weld is perfect; but a difficulty not yet mastered is that the fused iron is rendered porous, so that a tank electrically welded is not water-tight." We shall hope to learn that this difficulty has been effectually overcome, but at present it looks rather a formidable one.

A system of electric traction which is neither a secondary battery system, a conduit system, a conducting rail system, nor an overhead conductor system, certainly demands attentive consideration. If, furthermore, it should succeed in combining all the merits with none of the defects of these methods, we may venture to regard its future with some degree of hopefulness. Such a system we learn is now occupying the attention of Mr. Edison, who is busily engaged upon the first working models.

Meanwhile we are in a position to state that a system of the same or a similar character has already been devised in this country, and has already reached a stage of development considerably beyond that of "working models." Mr. Edison can so well afford to be forestalled in any single invention that we venture to hope that this intelligence will not give rise to any very severe strain upon his equanimity.

Mr. Edison, it is said, has given a large order in this country for nickel, with which he intends to construct a new type of pyro-magnetic generator. Probably no one capable of

Digitized by Google

forming an opinion on the question will be greatly surprised to learn that he has abandoned the hope of turning the earlier form of the apparatus to practical account. He finds, we are told, that the iron plates disintegrate very rapidly under the action of the heat reversals. It is true that nickel loses its magnetic properties at the comparatively low temperature of 350°C., but it is very difficult to believe the statement that Edison seriously hopes to improve the commercial value of the apparatus by the substitution of nickel for iron, seeing that the cost of the two metals may be taken in the ratio of about 30 to 1. According to Rowland, *Phil. Mag.*, 1873 and 1874, the maximum intensity of magnetisation of the two metals at 12°C. and at 220°C. is as follows :—

	At 12°C.	At 220°C.	
Iron and Steel	1,390	1,360	C.G.S. units.
Nickel	494	380	„

A pyro-magnetic generator built of nickel appears to us a rather fantastic conception.

THE Council of the Society of Telegraph-Engineers and Electricians has once more under its consideration the question of amending the style and title of the society and of increasing the frequency of its meetings. We sincerely trust that it will see the way to adopt both suggestions. We need hardly say that we shall be amongst the first to welcome any step which may tend to increase the influence or extend the usefulness of the society.

WE fear that the Gas Commissioners of Massachusetts must have been not a little perplexed by the contradictory nature of the scientific evidence laid before them by Prof. W. D. Marks on the one hand, and by Mr. W. F. Jenks on the other. They had under consideration the relative efficiency of distribution by transformers, and by the Edison direct system of supply. The learned professor put down for the alternating system an economy (? efficiency) of 56 per cent., allowing 70 per cent. for the dynamo, and 80 per cent. or less for the transformer, crediting the conductors, apparently, with 100 per cent. efficiency. But the Edison system up to two-thirds of a mile yields, according to this authority, "an economy from 60 to 100 per cent. greater." 100 per cent. greater than 56 per cent. is, we take it, 112 per cent., which is indeed something like "economy." But the learned Professor did not really mean this, for we find elsewhere that he puts down the Edison system at a modest 85 per cent. Now, however, comes Mr. Jenks (one of the engineers of the Edison Company) upon the scene, and it is distressing to a well-regulated mind to learn that a mere practical engineer should have presumed to differ from a Professor of pure and [mis]applied science. However, according to this gentleman, the average illumination obtained by customers of the Edison Company at Brockton was 120 candles for every horse-power developed at the central station when direct currents were supplied, while the company were prepared to guarantee as much as 160 candles on the alternating system.

IT is not a difficult matter to determine by calculation what should be the efficiency of an alternating system. The dynamo may be taken at 87 to 90 per cent.; add 3 per cent. of the output for the energy spent in exciting, and we get 630 watts for every horse-power developed. The mains must evidently be of so low a resistance as to make the drop of pressure insignificant, whilst a loss of 10 per cent. in the feeders will in most cases be an ample provision. This reduces the energy received at the primary terminals of the transformers to 567 watts. The efficiency of modern transformers can safely be reckoned at 95 per cent. at full and 85 per cent. at quarter output, or 90 per cent. average. Thus 510 watts will be available for the lamps for each actual horse-power developed at the station. With the liberal allowance of 3¼ watts per candle, this gives 158 candles to the consumer, so that the statement of Mr. Jenks is very near the mark, and his company should have no difficulty in giving the guaranteed illumination per horse-power.

FROM a letter in another column the world at large will learn that there is at length a prospect of the vexed question of primary battery lighting undergoing a serious development. We are sure that the advocates of other types of battery cannot afford to overlook the challenge of Mr. W. Webster, jun., who not only stakes his professional reputation on the merits of the Holmes-Burke type of cell, but adds a substantial sum in cash (to be paid to some deserving object). This looks like business, and we shall be most happy to render any assistance in our power to facilitate the competition. We have a convenient cellar for the batteries, and upon certain conditions we should be quite willing to allow the test to take the form of lighting the offices of this journal. We can take about fifty 20 candle-power lamps.

IT must be admitted that Mr. Wm. Webster, jun.'s, confidence in the Holmes-Burke cell rests upon the foundation of practical trials on a more extensive scale than those of any other battery for electric lighting now in the field. In five cases we could mention these cells have been employed for two years and upwards, and there are a good number in use which have been at work twelve months and under. The Eastern Telegraph Company have several of these batteries in use in their foreign stations, and we understand that they are giving satisfactory results.

IMPLICIT belief in one's own ideas is a good thing, no doubt, but it does not necessarily entitle a man to a reward of £500. Mr. Walsh, of Eclipse battery fame, however, evidently thinks otherwise. In a letter to *The Times*, referring to Mr. O. Lever's offer of a reward for a portable lamp, he says :—"Then I said to him (Mr. Kelly), 'that I had not got the slightest doubt that I would receive the £500 award.' He said, 'I hope you will—there is no doubt about it, you have got implicit belief in your invention.'"

WE take it that Mr. Walsh will certainly accept Mr. William Webster, jun.'s challenge, and then possibly we may see Eclipse first and the rest nowhere.

ANYBODY can quote scripture; but not everybody can play the characters well. One of our contemporaries, taken to task by a correspondent of another contemporary for claiming

Digitized by Google

to have originated the idea of an Electrical Association, and dropping it when it approached realisation, has retorted by insinuating that its critic is one of the unemployed seeking a berth in the new scheme! Assuming the prophetic mantle the aggrieved journal proceeds to say that "if we placed our hand upon the shoulder of him we suspect of being the author of the letter, and said unto him, 'Thou art the man,'" &c. Really, this is playing Nathan very ill. He did not put his hand on the king's shoulder, for that would have been a breach of good manners; he simply touched the offender's conscience, which is precisely what our irate contemporary fails to do. We have it on good authority that the writer of the letter was and is fully employed, and not at all anxious to add to his labours. In other words the prophet's pen has prophesied falsely, and the journalist's hand has fallen on the wrong man's shoulder.

OUR own concern in this matter leads us to make the further observation that it was David, not Nathan, who wrote saying, "Set ye Uriah in the forefront of the hottest battle, and retire ye from him that he may be smitten and die." Now, this is the *rôle* our retiring friends have been playing pretty well, and we make no complaint; but they cannot do that and the prophet all in one, with the part of Uriah and his ewe lamb thrown in.

PROBABLY most of our readers will feel a sensation of relief on learning that one of the most serious of the several law-suits with which the electrical engineering profession has recently been threatened is already settled out of court. We refer to the suit of the Anglo-American Brush Company in support of their claim on compound-winding. It may be remembered that in a supplement to *The Electrician* of October 2nd, 1885, dealing with the Brush Corporation's apparatus then to be seen at the Inventions Exhibition, Mr. Mordey gave a "characteristic" of a small Brush electro-plating dynamo constructed in the United States nine or ten years ago, which showed that Mr. Brush had thus early succeeded fairly well (considering the period and the character of the results at that time obtainable with even the best dynamos) in obtaining constant E.M.F. The general idea has been that Brush's object was simply to prevent currents from plating baths causing reversal of the polarity of dynamos. This result is no doubt obtained in compound machines, even if they are stopped while connected to the baths, if the series field winding is not too great, especially where cast iron magnets are used. But that this was not Brush's only object—that he wished to obtain constant E.M.F. in addition—was clearly shown in the article referred to, where attention was drawn to the fact that in the patent specification (No. 2003 of 1878) it was explained that a further purpose of the double winding was to enable the dynamo to do either a large or small amount of work. That is to say it was to deposit equally well on the articles in the bath whether those articles were large or small in number or in extent of surface—in other words, whether the current was great or small. That these conditions are "constant potential" conditions such as are usually aimed at in modern compound dynamos cannot be disputed; nor need it be explained that what applies to a plating vat, where all the articles were connected parallel, applies equally well to a circuit of incandescent lamps connected in the same manner—a method of electric lighting which, as a matter of fact, has been developed since the date of the compound-winding patent. It may be added that the patent is also of earlier date than the invention of the simple shunt-wound dynamo. That other uses than that of electro-plating would be found for this method of winding was indeed obvious, and was not lost sight of in the specification alluded to. We think that we are justified in regarding the final decision which the parties to the suit have had the good sense to arrive at as a fair and equitable one; and we congratulate the Brush Corporation on having obtained a recognition of its rights without the necessity of going into the courts.

HUMAN beings of the hum-drum common-place type have reason to be envious of the absolute confidence with which more highly-gifted mortals are able to regard their own achievements both present and prospective. How pleasant it must be, for instance, to be able to think and talk like this (we quote from an interview between a reporter of the *New York Herald* and a certain distinguished American electrician, whose name we shall forbear to disclose):—"I have solved the question of travel by electricity," said Mr. ——, "and I am now building an experimental [Why experimental ?] motor. There will, of course, be improvements in devices, but there is nothing further to be done in principle. That is complete, and leaves no question that we can travel between New York and Philadelphia, drawn by an electric motor, as rapidly and safely as by steam-power, and more cheaply. There is no guesswork about my assertion. It is so certain that I stake my professional reputation on having the trains running as soon as the patents are granted, the roads ready to make the experiments, and the motors built. Of course I cannot now make public the principle, but I may say that it differs from any of the existing methods of operating electric motors on railway lines. It is not merely a scientific possibility, but a practical, commercially available and economical solution of the problem of electric railway motors."

Tenders Wanted for Telegraph Stores.—In another column will be found an advertisement of the North-Eastern Railway Company, who are asking for tenders for the supply of Telegraph Stores.

The Channel Cables.—The Paris *Temps* denies the rumours circulated by the *Central News* with regard to the Submarine Telegraph Company's cables. According to the *Temps* the French Government have not yet renewed the concession, and consequently the English Government have not vetoed it.

Conversazione of the President of the Society of Telegraph-Engineers and Electricians.—The President of the Society of Telegraph-Engineers and Electricians and Lady Bright have issued invitations for a *conversazione* to be held on the 15th December in the Galleries of the Institute of Painters in Oil Colours, 191, Piccadilly.

The Electro-Harmonic Society.—The next meeting of the Electro-Harmonic Society will take place at St. James's Hall Restaurant (banquet room), at eight o'clock, on Friday, the

Digitized by Google

2nd December. This is a "ladies' night," and the programme arranged for appears to be fully up to the usual high standard of excellence of these enjoyable evenings.

Electric Light in Warfare.—It is a well-known military maxim that the side which first gets frightened loses the battle. In savage warfare the electric light is evidently capable of rendering excellent service in this direction. Witness the Reuter's telegram describing the terror of the Yonnies at the glare of the search lights during the recent fighting in Sierra Leone.

Clerkenwell.—Mr. J. W. King, of St. John's-square, informs us that he has lit his new gilding and plating works by electricity. The plant consists of an Edison Z type dynamo and a battery of Elwell-Parker accumulators. In his plating works he employs an Elwell-Parker and a Crompton-Bürgin converted machine, supplemented by various sets of accumulators. Motive power is derived from an Atkinson gas engine.

"The Electricians' Directory."—We shall be very pleased to receive from our readers any suggestions as to tables, &c., which might usefully be inserted in the forthcoming issue of "The Electricians' Directory," which will be ready at the end of December. This issue will be considerably larger than its predecessors, and suggestions of any kind for the improvement of the editorial portion will receive careful consideration.

Physical Society.—At the meeting of the Physical Society to be held at the Science Schools, South Kensington, on Saturday next, at three p.m., a paper will be read by Prof. S. P. Thompson, "On the Analogies of Influence Machines and Dynamos," and Mr. H. Tomlinson will read a paper "On the Thermo-Electrical Properties of Iron, when under Stress or Strain, by Raising the Temperature to a Bright Red."

The Electric Lighting of Trains in Germany.—Upon the Stuttgart-Hall Railway experiments are now being made in train lighting by means of Khotinsky accumulators and Bernstein lamps. A second battery is provided, which is being charged while the first is running down. The dynamo is driven from the axle of the guard's van, provision being made for automatic switching off when the speed falls too low.

The Edison Central Stations in America.— A New York journal gives a detailed list of 103 central stations in America which are equipped with Edison plant. The total number of lamps supplied from these stations is 313,300. Two stations (New York and Philadelphia) supply 15,000 lamps each, and there are half-a-dozen supplying 10,000 lamps, while the number with less than 1,000 lights is comparatively small.

Gas Engines employed in a Central Station Plant—At Spencer, Massachusetts, a Ball arc-light plant of 60 lamps is run entirely by gas engines. Three Otto engines, of 15 nominal horse-power each, are used. The plant is owned and worked by the local gas company, who thus manage to keep the business of lighting the town in their own hands, while utilising their own product. Very favourable reports are made of the successful and economical performance of the system at Spencer.

Settlement of the Action re Compound-Winding.—The important "compound-winding" action on the Brush patent, brought by the Anglo-American Brush Electric Light Corporation (Limited) against Messrs. Crompton and Co. has been settled. Messrs. Crompton have accepted the usual license, and agreed to judgment in favour of the corporation. The cross action brought by Messrs. Crompton on the Crompton-Kapp patent has been withdrawn, the Brush Corporation taking an assignment of that patent.

Taunton.—A deputation consisting of the local authorities of Weston-super-Mare recently visited Taunton for the purpose of viewing the electric light arrangements. They inspected the lighting of the streets, paid a visit to the engine room, and afterwards went to St. James's Church, which is illuminated with electricity. At five o'clock they partook of tea at the Castle Hotel, under the presidency of Mr. T. Penny, in the absence of the Mayor (Mr. S. Farrant). Speeches of a congratulatory and practical character were made, and the deputation expressed themselves greatly pleased with their visit.

University Extension Lectures.—The first of the series of lectures to be delivered by Mr. Lant Carpenter, at the Shoreditch Town Hall, under the auspices of the London Society for the Extension of University Teaching, and of the Gilchrist Trustees, was given on Monday last, the chair being taken by Prof. Stuart, M.P. The subject of this series is "Electricity in the Service of Man," illustrated by experiments and by the oxyhydrogen lantern, and the admission fee is one penny. The hall was filled with an enthusiastic audience of over 1,200 persons, and there can scarcely be any longer a doubt that the experiment is likely to be a highly successful one.

The Transmission of Power in India.—The *Times of India* contains a description of a remarkable engineering undertaking at Gokak, where three turbines, each of 250 horse-power, transmit power by rope gearing to a cotton mill at a distance of 739 feet, the first 300 feet being up the face of a perpendicular cliff. The work appears to have been carried out in an especially skilful manner. If we mistake not, this is the enterprise about which some correspondence took place in our columns with regard to the feasibility of electrical transmission. We should have been glad if the engineers had seen their way to this, but it must be confessed that a scheme of such magnitude would have presented a stiff problem to electrical engineers.

National Telephone Company's Conversazione at Glasgow.—The seventh annual *conversazione* of the *employés* of the National Telephone Company and their friends took place on Friday last in St. Andrew's Halls, Glasgow. Colonel R. Raynsford Jackson, chairman of the company, presided, and he was supported by Sir William Thomson, Mr. J. L. Mitchell, Mr. Wm. Alexander Smith, resident director; Mr. D. Johnstone Smith, district secretary; and Mr. Daniel Sinclair, resident engineer. During the proceedings a short speech was delivered by Sir William Thomson, who paid a high tribute to the National Telephone Company, remarking that he was not overstating the case when he said that the telephone had turned out as well in Glasgow as in any other place in the world, and it was better by far than in any other place of which he had personal experience.

A Foucault-Current Water-Heater.—One of the American companies has brought out an electric water-heater for use with alternating currents. It consists of an ordinary kettle having a rather thick bottom. When this is placed above an electro-magnet supplied with alternating currents, heat is produced by the generation of Foucault currents in the substance of the metal. This arrangement has some obvious advantages over the method of placing a resistance coil within the metal, but it is difficult to imagine that it can be equally efficient. A theoretical comparison of the amount of heat obtainable for a given expenditure of energy by the two methods would be interesting. It is useful to remember that 1,000 watt-hours is capable of raising 19·04lb. of water from 0°C to the boiling point, or of completely evaporating 2·95lb. of water from 0°C.

Digitized by Google

Glasgow College of Science and Arts.—The following excellent results were announced by Prof. Jamieson at the distribution of prizes which took place last week at the Glasgow College of Science and Arts:—The John Pender Gold Medal, or £5. 5s., for the best electrical engineering student taking the College diploma in electrical engineering, was gained by Jas. Raeburn, jun., now in Buda-Pesth, Austria. Eight students passed the technological examinations in electricity of the City and Guilds of London Institute. Of these one student took a prize of £5 and a silver medal in electric lighting; two students took a prize of £5 and a bronze medal, one in telegraphy, and one in electric lighting. Three took first-class honours in telegraphy, and the same number in electric lighting. Two gained second class honours in the latter subject. Numerous prizes and certificates were taken by students of the above College in mechanical engineering (City and Guilds of London Institute's examination) and in chemistry, practical geometry, naval architecture, machine construction, &c. (the Science and Art Department).

An Electric Type Writer.—We learn from a New York paper that considerable importance is attached to the appearance of a new instrument which is to compete at the same time with the mechanical type writer and with the telephone. The apparatus employs electricity as a motive power for actuating a type writer, which seems in other respects to bear a close resemblance to the instruments of ordinary construction; but by introducing electricity as an intermediary it is claimed that great evenness of action is secured, irrespective of the weight with which the keys are manipulated. The motion to and fro at the end of the lines is also purely automatic. But in addition to its use as a type writer the same instrument can also be employed both as a transmitter and receiver of telegraph messages. The receiving instrument does not require the attendance of an operator, but prints the despatch automatically. The instruments at both ends of the line print the despatch sent, and so a safeguard against mistakes is provided. It is claimed that the electric type writer will be valuable as a local aid to business, and offers many advantages over the telephone. One advantage claimed for it is that, no matter whether a person called up is at his place of business or not, the message can be printed through the medium of his type writer, and will be there for perusal on his return The despatches printed are in letter form, and not on endless tape. The instrument has been christened the "dynamograph."

Watt Arc Lamp is this?—We take the following paragraph from an esteemed contemporary, the *Bullionist*:—"On the invitation of the chairman (Mr. Hugh Watt, M.P.), we, on the 18th inst., visited the works of the Maxim-Weston Electric Company to witness in operation a small arc lamp, by means of which Mr. Watt claims to obtain five times the subdivision of light hitherto achieved by means of arc lighting. The lamp in question requires from 2½ to 3 amperes and 40 to 45 volts, giving about 150 candle-power. It will thus be seen that at least six lamps of this power can be obtained from one electrical horse-power. The invention consists in the arrangement of a series of wheels, levers, or other form of gearing for multiplying purposes, constructed on holders, frames, or bearings, so that the mechanism shall be held in check by means of a brake placed in a part of the electrical circuit, so that the carbons, when burning, are perfectly controlled. In other words, the lamp is so constructed that, when working, the current of electricity shall pass through the brake in such a manner as to show in and out of circuit, wholly or partially, the current; and, further, that the percentage of resistance shall be such as to prevent an undue shortening or elongation of the arc. Mr. Watt claims that by this means a steadier light will be obtained than by any known arc lamp; and also that the difficulty hitherto experienced in the lighting of large open or enclosed spaces, viz., the question of distribution at a low rate per lamp, will be overcome. He estimates that a large complete installation of the 'Watt' dynamo and lamp will not cost more than one half-penny per lamp per hour, while the present arc lamp costs something like five times that amount. Should the lamp in question answer the claims put forth regarding it, which it certainly seems to do, there is no doubt that it will tend in a very large degree to overcome the difficulty which has prevented our towns and cities being lighted by electricity on a large scale as in America, namely, the question of cost. The lamp, which will be known as the 'Watt' lamp, and the new 'Watt' dynamo from which it will be run, Mr. Watt claims are both in advance of any invention in this branch of electric lighting; and he further informs us that he hopes to be in a position to supply complete installations by 1st January next. The first batch of lamps are now in course of construction by this company."

The West India and Panama Telegraph Company.—*The Statist* explains the proposed scheme of reconstruction suggested at the meeting last week, and now under the consideration of the directors, as follows:—"The proposal is to cancel the £38,019 First Preference dividends overdue by an issue of like amount of First Preference capital, equal to £1. 2s. per share. The Second Preference capital and the accrued dividends on it are to be cancelled, and First Preference shares given instead in the proportion of 75 per cent., or £7. 10s. per share, in exchange for each £10 Second Preference Share and the dividends overdue thereon. The practical application of the scheme, it is explained, would be:—

First Preference.—Shareholders would receive per share an additional capital of £1. 2s. The present shares are quoted	£9	5	0xd
Valuing the reconstructed capital at £9 per £10 Share (to be within the mark), £11. 2s. capital would be worth	10	0	0
Showing an immediate increase in value per share of	0	15	0

On the basis of the dividends paid for the past year, it would take over seven years to liquidate the amount now overdue on the First Preference Capital.

Second Preference.—The price of these shares is nominally..	£6	0	0
In place of the present £10 Share and the accumulated dividend, holders would receive £7. 10s. First Preference Capital, which at £9 per £10 share would be worth	6	15	0
Showing an immediate increase in value per share of	0	15	0

No distribution has been made on the Second Preference capital for the past seven years and a-half, and as the company has, during the past twelve months, paid only one excess dividend of 3s. per share to the First Preference, and there still remains a sum of 22s. per share overdue, it follows on this basis that the holders of Second Preference Shares would not receive any dividend for the next seven years, until the arrears on the First Preference were liquidated. By the scheme proposed each £10 Second Preference Share would be exchanged for a freely marketable security now earning a dividend of 9s. per annum." We have reason to believe that there are legal difficulties in the way of carrying out this suggestion.

THE RISE AND PROGRESS OF TELEPHONY IN THE UNITED KINGDOM.

(Continued from page 533, Vol. XIX.)

At the close of the previous chapter it was mentioned that at the trial of the United Telephone Company *v.* Harrison, Cox-Walker, no serious attempt was made to show that the Reis transmitter interfered with the Edison patents as amended by the disclaimer of platinum contacts. It was otherwise with the contention that Philip Reis had anticipated the inventions of Graham Bell; on this issue the fight waxed hot and furious, and there are those who to this day contend that the judicial decision was not consistent with the facts of the case.

The learned judge had no difficulty in arriving at the conclusion that the "first Reis," as it was called (that is, the instrument consisting of a knitting needle surrounded by a coil, and placed upon a sounding board), could not be held to have anticipated the Bell receiver. The magnetic diaphragm which is the essential feature of the latter instrument is entirely absent from the former, and the alleged anticipation was held to have failed.

But the instrument upon which the defendants based all their hopes of upsetting the patents was the so-called "second Reis," which was illustrated and described in our last chapter, and which consisted of an electro-magnet with a bar armature held off by a spring, and carrying a wooden lath to reinforce the sonorous effect of its vibrations. Whether this bar armature did or did not constitute an anticipation of the diaphragm armature of Bell was the vital question at issue.

Before coming to a decision upon this point, however, the learned judge had first to consider the question whether or not "prior publication" had taken place in this country. It is generally understood that to invalidate a patent it is not sufficient to prove that the same discovery has been made at an earlier date, it must also be shown that knowledge of the invention had become public property. It has already been explained that our knowledge of "the second Reis" is solely derived from an illustrated description in the *Zeitschrift* by V. Legat (of which a full translation appears in Prof. Silvanus Thompson's book). No evidence exists, however, to show that this paper had been translated into the English language at the date of the trial, but it was proved that copies of the *Zeitschrift* had been filed in the usual way at the Patent Office Library, and in the Library of the Institute of Civil Engineers. Nevertheless, the only person who could be discovered in this country to have known of the existence of this paper was Dr. Muirhead, who seems to have made a careful examination of the contents. It may be worth while to mention that after the conclusion of the trial a correspondent writing to a contemporary journal called attention to what he believed to be a curious oversight on the part of the defendants, inasmuch as a description of Reis's telephone receiver appeared in the 1867 edition of "Ferguson's Electricity," pp. 257, 258. As a matter of fact this appearance had not been overlooked, as it is mentioned in the defendant's "particulars of objection;" but the instrument described by Ferguson is the "first Reis" and not the one described by Legat. This is perhaps a small matter, but as a mis-statement of a point of some importance it is as well not to allow it to go uncorrected.

The learned judge found some difficulty in construing the law as to what constituted prior publication, but eventually, "though not without some doubt," he decided that Legat's paper "must be considered to have been within the knowledge of persons skilled in these matters in this country." The way was therefore cleared for the more important question as to whether the Reis had anticipated the discovery of Bell. The judgment proceeded as follows:—"Looking at the plates it appears to me to be plain that the armature in Reis's receiver was not a disc at all, it was not a plate at all, but that it was a beam—a solid bar. When I say solid I do not mean that it was rectangular. It appears to me to have been a bar whose section was oval, and that is the result which is conveyed to my mind by the plate, and I think that the model which has been exhibited before me, in which that bar is converted into a twisted or curved disc, does not really and truly represent the instrument as described by Reis. I think, therefore, that the criticisms of Sir Frederick Bramwell on that model were perfectly well founded, and that there was nothing in the Reis which can be considered to have been an anticipation of the armature of the description indicated in Bell's patent. No doubt Reis's invention is coming near to the invention which was afterwards made by Mr. Bell, but it appears to me not to be the same; and I am not at all convinced that it will operate in the same way. It is perfectly true that there is some evidence before me that Reis's instrument will speak, but it does not appear to me that there is any evidence which shows that it could be made successfully to speak before Mr. Bell's patent was made known; and it is obvious that the advances which have been made in telephonic science, very largely in consequence of his discoveries, have enabled persons to use instruments in a manner which neither their inventors nor their users could have used them before the discovery; and I think this must be further borne in mind, that instruments as little like the true Reis as the ones that have been exhibited would, I have no doubt, apply within the description of Reis's instrument as being universal instruments."

(To be continued.)

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(Continued from page 7.)

It was noticed in the last paper that solutions of the perchloride and persulphate of iron yielded no deposit of metallic iron upon the cathode. It was next determined to ascertain the behaviour of a solution of the pernitrate of iron, employing the liquid at various degrees of concentration, with a current from two to five small Daniell cells progressively, the cells being arranged in series. The anode, as in the former cases, consisted of a plate of wrought iron, and the cathode a strip of sheet copper.

Pernitrate of Iron.—A concentrated solution of this salt was prepared by digesting fragments of iron in a solution composed of equal parts of nitric acid and water. On the following day the solution was ready for use. To form the electrolyte, for the first trial, five fluid drachms of the pernitrate solution were added to five ounces of water. Two Daniells were used, and the electrodes then immersed, their surfaces being about equal. During the first few seconds no apparent deposit took place, so the cathode was moved about quietly, when a slight film of iron began to form. The plate was then allowed to rest for about two minutes, at the end of which time it became coated with a thick black deposit, interspersed with bubbles of hydrogen, which rested firmly on the plate. Surrounding these gas bubbles were minute glistening particles of metallic iron, which had evidently been reduced by the hydrogen. The plate was now carefully rinsed so as not to disturb the coating, and was then held over the flame of a small lamp, at a moderate distance from the flame, until the black deposit became dry on both sides of the plate. During the process of drying, the deposit suddenly broke up into minute particles, leaving the copper surface exposed. The particles were then brushed off and collected upon a piece of white paper. Upon holding a magnet below the surface of the paper the granules were powerfully attracted, proving that they consisted of metallic iron in a very finely-divided state. A second plate was then immersed in the bath and allowed to rest for about five minutes, by which time it became very thickly coated with the same black deposit, which was afterwards washed, dried, and collected as before. An attempt was next made to induce the metal to deposit in a reguline form, by diluting the solution considerably. In this case, as before, a slight reguline film appeared upon the copper plate when it was kept in motion, but so soon as it was allowed to remain stationary the black deposit again formed, and after a few minutes' immersion it stripped off the plate (doubtless

Digitized by Google

dislodged by the hydrogen bubbles) and accumulated at the bottom of the vessel. The black deposit was afterwards collected, washed and dried as before, and the resulting black dust tested with the magnet, by which it was powerfully attracted. A still weaker solution was next tried, with a precisely similar result, and the plate was allowed to remain in the bath for about ten minutes, during which time the black deposit from the cathode accumulated on the surface of the liquid, nearly covering its entire surface in fact, the fine particles of iron being held in suspension by the hydrogen bubbles, with which it was intimately mixed. The solution eventually became nearly colourless, while the anode was but slightly acted upon. It should be mentioned that the evolution of gas was much more copious with the weaker than with the stronger solutions, while in some cases bubbles of gas nearly as large as a pea rested upon the plate for at least a minute before bursting. In reflecting upon the character of the dried deposit of iron above described, it appears to me to resemble the pharmaceutical product known as *Querenne's Iron*, which is prepared by passing a stream of dry hydrogen gas through red hot sesquioxide of iron contained in a gun barrel, the object of which is to reduce the iron in a very finely divided state, by which it may readily become dissolved by the juices of the stomach, thus forming a useful and effective chalybeate. The formation of *impalpable metallic iron* in the way I have indicated would be a far cheaper and less troublesome method than either of the processes adopted for preparing Quevenne's iron; indeed, I am disposed to think that the iron could be produced in a more finely divided state electrolytically than by the pharmaceutical methods.

Citrate of Iron.—A solution of this salt was prepared by dissolving recently-precipitated carbonate of iron in a moderately strong and hot solution of citric acid, the carbonate being added a little at a time until evidence of neutralisation occurred, which became known by the liquid remaining turbid after the last addition of the iron salt was made; an excess of citric acid was then given, not only to clear the liquid, but to assist the solution of the anode. The solution was used cold, and two small Daniells at first employed. A clean strip of sheet copper received a white and bright deposit of iron soon after the immersion, but as the deposit was scarcely rapid enough, a third cell was connected, when deposition took place freely upon a newly-prepared plate. After two hours' immersion a good bright deposit was obtained, which thickened at the lower edges in the form of minute nodules. The film, which was of a silvery whiteness, was of a thoroughly reguline character, excessively hard, and readily attracted by the magnet. On examining the anode, it appeared to have been very freely and uniformly acted upon. Five cells were next tried, when the deposit became more rapid, but still maintained its bright and silvery lustre, being even whiter than the best Damascus steel.

Cyanides of Iron.—The various cyanide salts of iron were tried, but not one of them yielded a reguline deposit of the metal. The only solution of this class which gave a tolerably successful result was that of the sulphocyanide of iron, from which a darkish film, of an iron-grey colour, was obtained upon a copper plate by keeping it continually in motion; no deposit appeared to take place upon a stationary electrode. While deposition was going on under these conditions a dirty white deposit formed upon the anode which was insoluble in the liquid.

Sulphate of Iron and Chloride of Ammonium.—A solution of the mixed salts has been applied by Meidinger and others for coating copper plates with iron. For this purpose the following proportions give very satisfactory results:—Sulphate of iron, 2oz., dissolved in water 1 pint; sal ammoniac, 1¼oz., dissolved in water 1 pint. These solutions were mixed, and a few drops of acetic acid added. With the current from two Daniell cells, and electrode surfaces about equal, a reguline deposit of iron was obtained upon a copper plate from a bath prepared as above immediately after immersion. There was but moderate evolution of gas, and the film was exceedingly uniform and of good colour, though neither so bright nor so purely white as the deposits from the simple sulphate or citrate salts. After half an hour's immersion, the coating, though otherwise faultless, assumed a dull appearance; there was no blackening at the edges of the plate, however, nor any other irregularity of the surface of an objectionable nature. There was a slight deposit of peroxide, however, which would doubtless continue to form, but since this readily finds its way to the bottom of the vessel it does not necessarily interfere with the film, provided the liquid be kept in a deep vessel and the deposited oxide allowed to remain undisturbed when immersing or withdrawing the coated plates. On examining the anode (a plate of wrought iron) it appeared to have been pretty uniformly acted upon, and exhibited the characteristic crystalline appearance of iron which has been subjected to the solvent action of weak acid solutions. The deposit upon the cathode, after one hour's immersion, had become somewhat more dull, but otherwise the coating was perfectly uniform and of good quality.

Protacetate of Iron.—A solution of this salt was prepared by dissolving freshly-precipitated carbonate of iron in dilute acetic acid, of which it is a ready solvent. The carbonate of iron was added in moderate quantities at a time, until the acid became neutralised, when a small addition of free acetic acid was made, and the bath, after filtering, was ready for use. The current from three small Daniells was employed, and the surface of the positive electrode was about three times that of the cathode. Under these conditions a good white deposit was promptly obtained, the film being of a perfectly reguline character. After a short immersion of the electrodes the anode was examined, and proved to have been freely acted upon. There was a slight disposition for the deposit to blacken in the centre of the negative plate, which was remedied by immersing a larger surface of anode. The deposition was now allowed to proceed undisturbed for about two hours, at the end of which time it was found that the solution had become considerably oxidised, there being a copious deposit of peroxide of iron at the bottom of the vessel; at the same time the deposit had lost its reguline character, and became black and pulverulent, while the anode was considerably eaten away.

Sesquiacetate of Iron.—A solution of this salt was prepared by dissolving freshly-precipitated hydrated sesquioxide of iron in acetic acid, the solution being afterwards moderately diluted and filtered. There was practically no deposit obtained from this solution, even when brisk motion was given to the cathode.

Ammonio-Chloride of Iron.—A bath was prepared by adding to a solution of perchloride of iron another of chloride of ammonium, the combined liquids being of moderate strength. Five cells were used, and a large anode surface exposed. On immersing the negative plate (a strip of copper) it received a partial coating of a dark colour, but while the plate was stationary in the liquid there was practically no deposit. When the plate was briskly moved about a slight film appeared all over the immersed surface, which was black at the lower corners; beyond this there was no deposit obtainable. The solution was next diluted with a considerable proportion of water, when the plate became coated with a black film of iron in a finely-divided state, similar to that obtained from the pernitrate, but much more slowly formed. The results, however, had no practical significance.

Oxalate of Iron.—A solution was formed by dissolving freshly-precipitated carbonate of iron in a strong solution of oxalic acid. The iron salt dissolved very freely, with evolution of carbonic acid, leaving a clear solution, which was next diluted with water. With two Daniells no deposit took place upon a copper cathode while it remained stationary in the liquid; when this electrode was briskly moved about, however, a white film of iron was obtained, which gradually increased in thickness so long as the agitation was kept up. During the electrolysis the solution became decomposed, and a deposit of peroxide settled at the bottom of the vessel. Five cells were also tried, but there was no deposit of reguline metal unless the cathode was kept in brisk motion.

Ammonio-Citrate of Iron.—A solution of this salt was prepared by first dissolving recently-precipitated carbonate of

Digitized by Google

iron in a strong and hot solution of citric acid; the solution was then allowed to cool, when liquid ammonia was added, and the solution was then ready for use. With the current from five small cells a copper plate received a bright silvery deposit of iron immediately after immersion, and maintained this character for some time; but, owing to the anode not becoming freely dissolved, the solution eventually yielded its metal very slowly.

Ferrate of Potassa.—A deposit of iron may be obtained from a solution of this salt, by using a moderate current, but the liquid soon decomposes with the formation of peroxide of iron.

Sulphate of Iron and Sulphate of Magnesia.—For obtaining electrotypes of iron, MM. Jacobi and Klein first deposit a film of copper upon lead or gutta moulds in the usual way, and after well rinsing they are at once placed in a bath composed of sulphate of iron 139 parts, sulphate of magnesia 123 parts. These are dissolved together in hot water, and a little oxalic acid, as also some iron shavings added. The solution is kept in a well-stoppered bottle or carboy, in its concentrated state, and when required for use is diluted with water until its solution has a specific gravity of 1·155 (water being 1,000). In working this solution oxide of iron forms on the surface of the liquor, which must be skimmed off with some of the solution and shaken up in a bottle with a little carbonate of magnesia, and after settling the clear liquor is returned to the bath. The iron deposited from this bath is very hard and brittle, therefore the electro deposit must be carefully handled when separating it from the mould. The copper is removed from the surface of the electrotype, either mechanically, or by dipping it in strong nitric acid.

Ferrocyanide of Iron.—The following solution, devised by Boettger, for coating engraved plates, is probably the only cyanide preparation of any practical value:—Ferrocyanide of potassium 10 grammes, Rochelle salt 20 grammes, are dissolved in 100 cubic centimetres of distilled water. To this is added a solution composed of persulphate of iron 3 grammes, dissolved in 50 cubic centimetres of water. A solution of caustic soda is next added, drop by drop, with constant stirring, until a perfectly clear liquid is obtained of a light yellowish colour. This solution, which would have little action upon an iron anode, would require to be constantly strengthened by the addition of concentrated liquor.

Chapter II.

Batteries.

(Continued from page 31.)

11. In the Daniell cell the difficulty of polarisation is overcome by surrounding the copper plate with a solution of sulphate of copper, so that the hydrogen at the moment of its development, instead of accumulating on the surface of the plate, attacks this copper sulphate, turning out the copper, which deposits on the plate as a metallic layer, and chemically takes its place, forming hydrogen-sulphate—*i.e.*, sulphuric acid. The plate is thus kept clean during the action of the cell by the addition of pure metal, while the sulphate of copper is consumed and the solution acidulated. Under these circumstances scarcely any polarisation (*see* para. 10) takes place, and the E.M.F. of the cell is nearly constant under every rate of current supply. It is convenient to remember that the volt (*see* para. 4) is approximately the E.M.F. of one Daniell cell. Even with care in the choice of pure materials and in the strengths of solutions, differences of as much as 2 per cent. will be found in the E.M.F. of a series of cells, but the average under most favourable conditions is 1·08 volt each.

12. This cell's chief disadvantage lies in the fact that zinc, like hydrogen, decomposes copper sulphate, forming zinc sulphate and throwing out the copper. If, therefore, any of the copper sulphate solution reaches the zinc plate it is immediately converted into zinc sulphate, and the copper is thrown down upon the plate. Each separate particle of copper so deposited sets up by contact with the zinc plate a separate E.M.F., by which a local current is established, flowing from the particle through the area of contact to the plate, and from the plate back to the particle through the

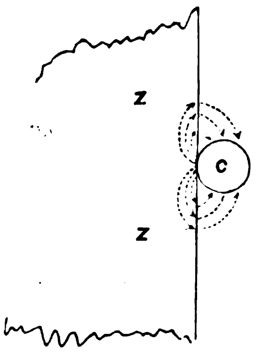

Fig. 2.

surrounding solution, as shown in Fig. 2, which gives a magnified representation of such a particle, C, on the surface of the plate Z. This local current continues as long as the contact between Z and C is maintained, and the zinc in the vicinity of the particle is consumed, while the main current of the cell, receiving no accession through this source, is rather impeded by the obstacle C. This local current, decomposition, and wasted consumption of zinc is termed *local action.* It is clear that any metallic impurity in the zinc plate, and at its surface of contact with the solution, tends to set up local action; and a plate of zinc containing such impurities consumes irregularly in action, and will show signs of pitting after merely remaining plunged in water for some time. Local action due to metallic impurity may be got rid of by cleansing the zinc plate and rubbing it well with mercury—amalgamating it, as it is termed. The superficial amalgam or alloy of zinc so formed has practically the same E.M.F. with copper as unprotected zinc, but the impurities are kept covered and separated from the solution by a metallic film of mercury, and no series of metallic contacts in a circuit from which liquids are excluded will give rise to an E.M.F. Impurities, however, that are deposited from without—as, for example, particles of reduced copper from stray copper sulphate in the solution round the zinc plate—are not so readily imbedded in the mercuric film as to pass out of free contact with the solution, and so local action from this cause takes place in spite of amalgamation.

13. It would, of course, be possible to prevent the copper sulphate solution, surrounding the copper plate, from straying into the neighbourhood of the zinc, by setting a partition or barrier of impervious substance between the plates, thus keeping them and their solutions entirely separate; but if this partition were of non-conducting material it would effectively prevent the current set up by the cell's E.M.F. from passing between the plates, and if, on the other hand, it were of conducting material, such as metal, then hydrogen would be thrown up on its surface, and polarisation would take place, so that the plan of introducing copper sulphate would be rendered useless. The difficulty is met by employing a partition of porous earthenware, a material in itself non-conducting, but containing numerous small channels, which become filled with liquid, so that, while the solutions on each side are kept apart, no great obstacle is interposed to the passage of the current. Cells which thus employ a separate solution for each plate are called double-fluid cells.

14. All such porous partitions do, however, allow the liquid solutions they separate to permeate and mingle to a greater or less extent, the process of so doing being termed *diffusion.* This diffusion takes place more slowly as the density of the separated solutions becomes more nearly equal, and as the

Digitized by Google

porous barrier becomes thicker; but by increasing this thickness we add to the obstruction which is offered to the current in traversing the partition. This obstruction is termed *resistance*, and as electricity flows in virtue of E.M.F., so that flow is obstructed and diminished in rate in virtue of resistance. The flow of water presents an analogy, for if a current of water be flowing through a pipe from one tank to another owing to a difference of level at which the water stands in them, the rate of flow will depend, assuming that difference of level artificially maintained, upon the dimensions of the connecting pipe. By altering the length and calibre of the pipe, or by altering, as with a tap, the amount of obstruction in it, we can make the current of water as great or as small as we please; in other words, we can make the quantity of water which passes through the pipe in a given time as great or as small as we please. Just in the same way, having a certain E.M.F. in a circuit, we can, by increasing or decreasing the resistance in that circuit, make the current generated by the E M.F. as great or as small as we please; or, in other words, we can alter at will the quantity of electricity which passes through the circuit in a given time. A good conductor, offering little obstruction to the passage of an electric current, has little resistance; while a bad conductor is one that has, on the contrary, great resistance. We shall consider the nature of resistance more fully at a later period, but it will at present suffice to observe that it is measurable in terms of a definite unit, called the *ohm*, after the German scientist of that name. An ohm is roughly the resistance offered by a column of mercury one metre long and one square millimetre in section, or of 140 yards of ordinary No. 8 overhead iron telegraph wire, or of 200 yards of ordinary cable core, whose conductor weighs 120lb. per nautical mile; in other words, each of these three lengths of conductor would offer approximately the unit amount of obstruction to the flow of electricity through them.

15. We have seen that the Daniell cell, owing to the diffusion of its solution, infringes the second condition of Article 5, page 30, by the waste of material which goes on when the cell is not at work, but it has otherwise so many advantages that various forms have been adopted for different purposes and conditions of current supply.

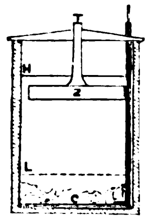

Fig. 3.

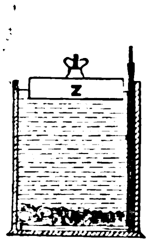

Fig. 4.

16. One of the simplest types is the gravity Daniell, shown in section in Fig. 3. In this cell the solutions are kept apart by gravitation only, the solution of copper sulphate being denser than that of zinc sulphate. A flat plate of copper, C, is therefore placed on the floor of the cell as the negative element, and covered with crystals and solution of sulphate of copper up to L, about one-fourth of the cell's height. The zinc solution of acidulated water or sulphate of zinc is then carefully added, and the zinc plate Z supported last of all a little below the surface H. Diffusion of the solutions proceeds rapidly if the cell is out of action, but sustained work tends to keep the diffusion in check owing to the more active consumption during current supply. The cell is therefore well suited for yielding continuous currents, and has always been much in favour for telegraphic purposes in the United States, where the circuits are worked on the closed-circuit principle—that is to say, with the current from the battery always flowing to line except in the spaces or pauses of manipulation, separating the signals.

17. The Minotto cell is a derivative of the gravity type, more especially adapted to transport and discontinuous work. It is represented in section in Fig. 4. The outer cell is commonly of gutta percha, which is a substance less liable to injury than glass. Above the copper plate and sulphate crystals wet sawdust is packed, and the zinc plate rests above the sawdust with the pressure of its own weight, and with its upper surface about level with the top of the cell. Whereas the gravity cell cannot be moved without disturbing the solutions and assisting their diffusion, the Minotto suffers little by transport. The sawdust takes the place, in fact, of the porous earthenware partition in the typical Daniell cell. The internal resistance is, however, greater, varying from ten to thirty ohms per cell, according to the quality and packing of the sawdust. If the cell is first set up with sawdust soaked in fresh water, the internal resistance (*see* para. 14) will be 100 ohms or more, until by working the zinc sulphate and sulphuric acid have time to form and impregnate the sawdust. The cells, if made up in this way, should therefore be left on *short circuit*, *i.e.*, with the poles (*see* para. 8) directly connected for twenty-four hours or so before they are brought into use. If required to be set up for more immediate use, the sawdust may be soaked in acidulated water. They tend to increase in internal resistance after a time, owing to the drying up of the sawdust, and fresh water has to be added when necessary, the right condition of moisture existing when the sawdust is thoroughly saturated, and a layer of liquid just rises round the base of the zinc.

18. The Thomson tray cell is another form of Daniell, of the gravitation type, specially adapted for supplying strong and continuous currents. Shallow trays, 22in. square and 2¾in. deep, form the outer cell. A square sheet of copper rests on the floor of the tray, and the sulphate of copper in crystal and solution rises above to a height of some 2in. The zinc plate, in the form of a stout grating 16in. square, shown in section at

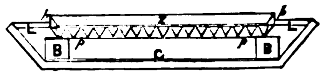

Fig. 5.

Z in Fig. 5, is supported horizontally on stoneware blocks, B B, at the corners of the tray. Stout parchment paper, *p p*, covers the lower surface and sides of the zinc grating to assist in separating the solutions, on the principle of a porous diaphragm, and the zinc solution, fresh water, or, preferably, a solution of sulphate of zinc, is poured in above until the upper surface of the grating is covered to the depth of about one quarter of an inch. The resistance of these cells is about one-tenth of an ohm each, or even less when in good working order. They require charging with sulphate of copper at regular intervals, and the density of the zinc sulphate solution should also be kept down to a density of 1·12, or about one-quarter saturation, by partly drawing off from time to time, and replacing with fresh water.

The British Iron Trade Association.—The following extract from the printed rules of the above association will prove interesting to electrical engineers at the present time:—1. The general objects of this association are—To secure a means of communication between members of the iron and steel trades of Great Britain upon all matters bearing upon the commercial interests of these industries. To attend to all matters connected with foreign tariffs, commercial treaties, and home Parliamentary business that may have a bearing upon the position of the iron and steel trades—excluding questions affecting the regulation of wages or of a purely local character—and generally to take all proper measures for advancing the interests of the British iron and steel trades in their various branches. 2. All persons, firms, and incorporated companies connected with the iron and steel industries in the British Islands, Colonies, or dependencies may become members of the association, subject to such payments and bye-laws as may from time to time be approved by the general council.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December next.

The EDITOR *will be glad to receive new names for insertion in the* DIRECTORY *as soon as possible, but not later than December 1.*

All particulars relating to Advertisements will be at once forwarded, on application.

VOLUME XIX.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

THE TRAINING OF ELECTRICAL ENGINEERS.

There comes to us from the electrical trades in America a complaint which, if we are not greatly mistaken, will soon be echoed in this country with even greater vehemence—the complaint, namely, that the supply of trained and skilled electrical engineers does not satisfy the requirements of the profession. Our New York contemporary, *The Electrician and Electrical Engineer*, alleges that hardly any corporation or firm engaged in electric light and electric power is able to man its work adequately; and adds that it is easier to get business than to execute the work. The deficiency is apparently not so much in the quantity as in the quality of the new candidates, the demand increasing faster than the supply, "notwithstanding the influx to that [electrical engineering] vocation of large numbers of young men during the past few years, and the successful establishment of electrical courses in many of our high-class technical schools."

Speaking for this country, we cannot say with equal confidence that it is easier to get work than to execute it; but we speak well within our knowledge of facts when we state that here, as well as in the States, the demand for skilled assistance is greater than the supply. Further, we agree that the need is most felt in the higher branches of the profession, for which a scientific education, combined with technical, and especially mechanical knowledge are much to be desired, but very hard to find. In this country, however, it is not so much men competent to design a dynamo or equip a central station that are lacking, but rather men who may be trusted to carry out on their own responsibility the details of schemes entrusted to them requiring some scientific knowledge but a good deal more common sense and mechanical aptitude. Where we venture to differ from our contemporary is in the remedy it proposes, or rather counts upon, to meet

Digitized by Google

this crying want. It is true that the money value of the required knowledge and skill is an attractive element in the problem; so attractive, indeed, that there is no lack of aspirants. What we take leave to doubt is the character of the men so attracted, and we altogether demur to the proposition that the "ample compensation" held out to them will, by increasing their numbers, add anything to the capacity and efficiency of the source on which we are at present depending for recruiting the profession of electrical engineering.

The article from which we have quoted bears out our misgivings, for in effect it says, notwithstanding the vast amount of training afforded by "high-class technical schools," the material turned out is not exactly what is wanted. We hear precisely the same objections urged in this country; and that being the case it is idle to rely on the growing attractions of the profession. "Bring in more heads to count" is a nostrum that finds little favour outside the sphere of politics, and we are quite sure that in matters of business it deserves none. What we want is not more students, but a better system of training them.

Our own belief is that the electrical engineering profession must for some time to come draw its reinforcements from older and kindred professions where practical knowledge has been acquired already, and where all that remains to be learned are the science and technics of the newer industry. As a matter of fact this is what has happened so far, the best recruits to the electric lighting business being men who have come to it as mechanical engineers and then taken the trouble to study the science of electricity. The supply from this quarter naturally does not keep pace with the demand; and there has consequently arisen a cry for the science and technical colleges to meet the deficiency, a cry which, we hasten to admit, every effort has been made on the part of their professors to satisfy by the best methods at their command. But we have said before, and we repeat it now, after inquiry among firms which have accepted young men from these colleges, that the methods are not the best calculated to provide what the workshop is in need of. Accustomed only to a long course of science classes or college lectures, the student treats the machinery merely as new appliances to experiment with, and the whole establishment as a sort of enlarged laboratory constructed for his special edification.

It is not surprising that coming to his work in this spirit the student remains a student, and the sooner he leaves as a student the better for himself. The fact may then dawn upon him and all concerned that he has begun at the wrong end. He ought to have gone to the workshop first; learnt the practical business young; and, what is of far greater value, learnt self-reliance, manliness, and how to battle with the world. Then, and not till then, he may seriously engage in scientific studies, for he will then be able to take them up wisely—that is, with a sense of the practical uses to which he can turn them to account. Instead of this, we are launching inexperienced young men upon a career for which they may be wholly unfitted, and for the pursuit of which they have missed all those years of preliminary practical training which enable men younger in years but older in experience to beat them out of the field. No wonder they fail, and no wonder their master is beginning to tell his friends that he would rather pay a good salary to a competent mechanic than take in a certificated student with a handsome premium.

For a purely scientific vocation the college training is, of course, an indispensable beginning; but what we are dealing with is a matter more nearly related to pure business than to pure science. We rather fancy that an ASSOCIATION OF ELECTRICAL ENGINEERS, which has been advocated in these columns for some time past, would have something useful to recommend in this relation. Members of such an association would know pretty well what they wanted in the shape of learners; and would not be long in agreeing as to the best mode of getting and training them. One of our contemporaries in opposing the projected association has sneered at the idea of creating a sort of diploma without which nobody could practise the profession of electrical engineer. That idea has never been entertained; but the reality is more easy of attainment than our critic seems to remember. The letters C.E. and M.S.T.E. are not diplomas; but they count for a good deal, and perhaps, notwithstanding the ballot boxes which confer the distinctions, for a good deal more outside the Institution than inside. Some care in selection is legitimately exercised in all such corporations, and the best road to the distinction will always be through a practical course of training. We very much suspect that the Technical Colleges are not supplying diplomas which the world at large will recognise, whereas an Electrical Association could and would supply them to the right sort of people; and in that case the responsibility for ignorant and incompetent pretenders would rest, not on the trade, as at present, but on the public if it chose to employ them.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

The step which was taken a fortnight ago has resulted in a well-nigh unanimous expression of approval of the outline scheme which has been laid before our readers. Of the total number of replies to our recent circular which have been received up to date we find that

89 per cent. express approval,
8 per cent. prefer to await further developments before offering an opinion,
and **3 per cent disapprove.**

It is necessary to remark that the issue of the circular was confined to those firms and individuals whose names appear in "The Electricians' Directory" under the head of "Electrical Engineers" (which includes a certain number of "consulting" electricians) and of "Electric Light Engineers and Contractors."

The list in the "Directory" naturally includes a tolerably large proportion of electric-bell and apparatus makers and retail dealers. And excluding those names which, although appearing in these lists, are not otherwise of any importance in this connection, we find that 80 per cent. of the electrical engineers of London and the provinces have up to this date favoured us with a reply.

A large number of suggestions, some in our opinion of great value, have been received. Of these, perhaps the most immediately important and those which we have reason to know commend themselves most strongly to the majority of leading men in London, are (1) that the Association should be one of the Electrical *and allied* Industries, with the object principally of including those mechanical engineers who design engines, &c., especially for electrical work; and (2) that the Association should be one of individual members, and *not* of firms and companies in their corporate capacity.

In confining the issue of the circular to the Electric Light and Power Engineers, it has not been our intention to influence the exclusion of Telegraph and Telephone Engineers, but we have simply wished to leave this an open question for the after consideration of those most immediately concerned. We may mention that, altogether apart from the opinions scheduled above, we have received several letters from telephone men expressing a desire to support the movement, and we may instance the case of the Managing Director of one of the

Digitized by Google

most important provincial telephone companies, who wrote that sixty members of his staff would wish to join.

We have only to add that our own responsibility in the matter, so far as it has been of an individual character, may now be considered to have ceased. Active steps are being taken in influential quarters to further forward the movement, and it may practically be taken for granted that the announcement of a public meeting, at which all who are interested for or against the scheme will be invited to attend, will shortly follow.

AN AUTOMATIC REGULATOR FOR CONSTANT CURRENT OR CONSTANT POTENTIAL.

The regulator which we are about to describe presents nothing especially novel in principle, being, in fact, merely an automatic switch for varying resistance in the field-circuit of the dynamo (as, for instance, in the well-known Goolden and Trotter apparatus); but when we add that the design is due to MM. Jehl and Rupp, our readers will naturally expect to find both originality and ingenuity in the treatment of the details. The chief difficulty to be overcome in apparatus of this description is the avoidance of "hunting," and this it will presently be seen is effected in the apparatus in question in a very ingenious manner. In the notes before us, the designers claim that the arrangement is both simple and reliable. It must be admitted that at first sight of the adjoining figures the claim appears a somewhat doubtful one, but on a closer examination we are inclined to think that it will be admitted that the details are not nearly so formidable as they appear.

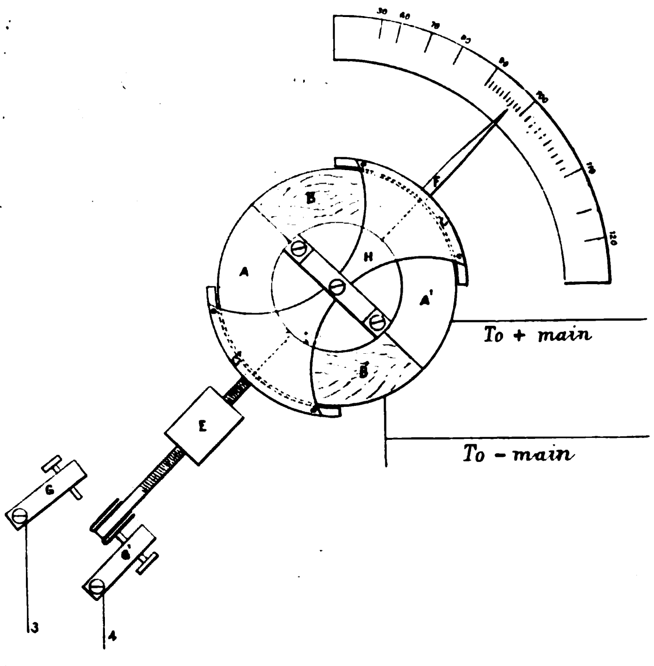

Fig. 1.

Fig. 1 shows the relay by which the movements of the switch are controlled. It is scarcely necessary to say that for constant current the coils are wound with large wire and placed in the main circuit, while for constant potential they are connected as a shunt across the terminals of the machine. The relay consists of two quadrant pieces of soft iron A A′, together with two quadrants of wood or other insulating material B B′. The disc thus formed is of some thickness, and has a groove cut around its edge, which is filled with wire. When a current passes through the coil we have, therefore, a short cylindrical magnet, the two quadrants on each face having the same polarity. A soft iron needle or armature, C C′, is pivoted at the centre, on a brass bridge, H, and is shaped also in quadrant form. The whole arrangement resembles in outline a quadrant electromotor. A pointer, F, extends from one of the armature quadrants, while the other carries a projecting rod, upon which is screwed a counterpoise, E; this can be adjusted to any desired position. At the lower end of the rod are two platinum contact springs, D, shown by the heavy lines in the figure. The rod is also connected with one of the terminals of the coil of the relay, and forms part of a circuit, which is a shunt upon that coil. The instrument is fixed upon a vertical support, and tilted as shown; the weight is then adjusted until the distance traversed by the pointer between the limits of the permissible variation of the E.M.F. (or current) tends to be as great as possible, so as to enable the springs D to make firm contact. The scale of deflection is usually very irregular, as seen in the figure. At G and G′ are contact pieces, with one or other of which the platinum springs make contact when the limit of variation is exceeded in either direction.

These contact pieces are connected by the wires with the studs E and E′ (Fig. 2). Attached to these are spiral springs, and

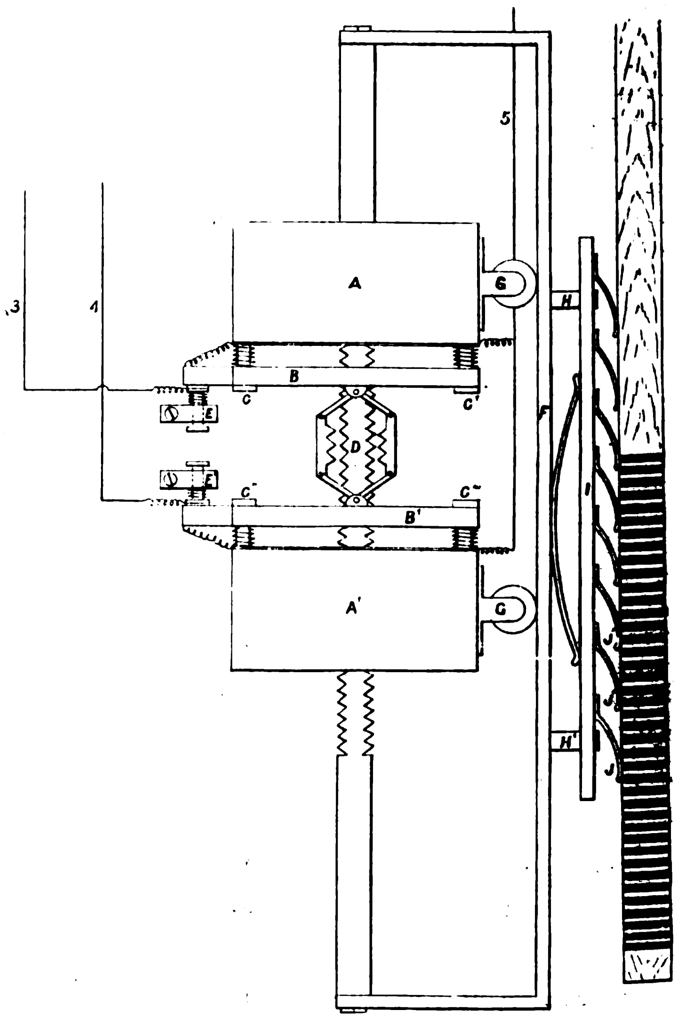

Fig. 2.

against these springs rest the armatures B B′. On its way to the coils of the electro-magnets A A′ the current passes through the studs and springs and across the armature itself. If, then, the armature is attracted its first movement towards the magnet is followed by the spiral spring, but when this has completed its extension contact is broken, and the magnet loses its power. The action is precisely that of an ordinary electric bell make-and-break.

The magnets A A′ (Fig. 2), which actuate the switch and place resistance in or out of the field circuit, are of somewhat peculiar construction. They consist of a circular disc or cylinder of soft iron, in which a groove is turned on the flat side, and which is also bored out in the middle. A diametral cross

Digitized by Google

section is shown in Fig. 3. The coils are wound on a former and dropped into the groove B B′ (Fig. 3). We thus obtain a compact ironclad magnet, having one polarity at the centre and the other around the circumference, both poles being annular in form. A circular disc of brass, having a central aperture, is laid over the face, and not only serves to hold the coil in place but also prevents the sticking of the armature. Two of these magnets are placed face to face some little distance apart, and each is provided with a similar armature. The latter is also annular in form, and is held in position by pins c c′ c″ c‴, which pass through small holes in the margin of the flat ring. Upon these pins are mounted spiral springs which resist the approach of the armature to the poles.

A brass rod, D, passes through the central aperture in both magnet cores, and is provided with ratchet teeth along the middle of its length. To each armature is attached, as shown, a sort of jointed parallelogram gripper, having three teeth on either side.

The action will now be easily understood. If the relay closes the circuit of the magnet A, the armature B is attracted and moves upwards; the gripper closes with the rod D and shifts the contact frame (F, H, and I) in the same direction. But the next moment the circuit is broken at E, the armature falls back, opening the gripper, and allowing the contact frame to remain at rest. The circuit is again closed at E, and the frame is shifted further forward until the potential has been adjusted so as to allow the relay to finally open the circuit. The repeated small adjustments are, of course, effected with great rapidity; but an adjustment of this intermittent nature is undeniably the most effectual cure for "hunting."

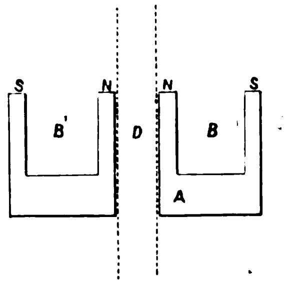

FIG. 3.

It is scarcely necessary to describe the remaining features; 5 is the wire completing the shunt circuit of the magnets and the relay rod. G G are rollers on which the moving frame slides; at F a bow spring presses outwards the part I, which carries the contact spring J J′ J″. Resistance is cut out by short-circuiting, so that there is no sparking at these points.

EXPERIMENTS ON THE POSSIBLE ELECTROLYTIC DECOMPOSITION OF CERTAIN ALLOYS.*

BY PROF. W. C. ROBERTS-AUSTEN, F.R.S.

The original suggestions framed for the guidance of the committee provided for an examination of the question whether molten alloys would conduct electrolytically, and during the year 1886 various experiments were made in the Mint laboratory, the results of which were in all cases negative, but were useful as indicating the method of working which appeared to afford the best prospect of success. The selection of a suitable alloy is by no means easy. It seemed well to begin by employing lead-gold and lead-silver alloys for the following reasons:—Matthiessen† has shown that these alloys, when considered from the point of view of their electrical resistance, belong to a class described by him as "solidified solutions of one metal in the allotropic modification of another."

Some work has already been done on the alloys considered as solutions of the precious metals in lead. I have already submitted to the British Association preliminary results on the diffusion of silver and of gold in molten lead,* and some unpublished experiments of my own have shown that certain silver-lead alloys when poured in spherical moulds, capable of holding about 2·6 kilogrammes of lead, set as a whole without exhibiting any tendency to the re-arrangement of the constituent metals known as "liquation"—that is, the constituent metals do not readily fall out of solution. Such alloys are those which contain less than 3 per cent. of silver. The alloy containing 51·06 per cent. of silver, to which the formula Ag_2Pb may be assigned, also sets as a whole without rearrangement of its constituents. Guthrie, in an admirable research, interrupted by his lamented death, has shown† that a "Eutectic" alloy of silver and lead probably contains less than 1 5 per cent. of silver—that is, it is the alloy of the lead-silver series which has "a minimum temperature of liquefaction, . . . a temperature lower than that given by any other proportion," and he points out that such eutectic alloys are "neither atomic nor molecular" in constitution.

The curves representing the electrical resistance of *solid* lead-silver and lead-gold alloys are continuous, and do not reveal the existence of any special alloy differing widely in resistance and in physical properties from the rest of the series. In the case of the copper-tin series of alloys, investigated by Matthiessen‡ in 1860, by myself§ in 1879, and by Dr. Lodge‖ in the same year, the alloys $SnCu_3$ and $SnCu_4$ stand quite apart from the rest of the copper-tin series both in colour, lustre, and electrical resistance.

It will be specially important to ascertain whether the passage of a strong current will enable the constituents of the copper-tin series of alloys to be separated, but unfortunately the alloys of these metals have high melting-points, and as the alloys have to be kept molten by the external application of heat during the passage of the current, the difficulties of manipulation are greatly increased. I considered, therefore, that it would be better to begin with the lead-silver and lead-gold series, which have comparatively low melting-points, and of which, as I have already stated, much is known concerning their behaviour as solutions. One additional advantage in the employment of these alloys is presented by the readiness with which variations in their composition may be determined. This is a point of some importance, for if, as Dr. Gladstone has already suggested, the results of passing the current through the molten alloys were only very slight changes in composition, the errors of analysis might overshadow the change. In the case, however, of the lead-gold and the lead-silver alloys, the method of assay by cupellation enables very minute changes in composition to be detected, and the amount of change can be determined with great readiness and accuracy.

The preliminary experiments need not be described at length; it is only necessary to state that fire-brick U tubes, about five millimetres in section, were employed, and that in them the fluid alloy was kept molten by the external application of heat. The electrodes first used were stout iron-wire terminals of a forty-pint cell Grove battery; the passage of the current was maintained for thirty minutes, and portions of metal were tilted out from either end of the tube. These samples were then assayed, and it was found that no variation whatever had been produced by the current. The passage of the current was not maintained during the time the samples were taken, and, as diffusion would probably rapidly restore the uniformity of the alloy, if the current did produce any change, care was taken in subsequent experiments to remedy this defect in the manipulation.

Dr. Lodge, in a letter to me dated April 5, 1886, asked whether it was possible to employ tubes one millimetre in section. I therefore broke off the bowls of two tobacco pipes, leaving about ten millimetres of stem attached to each of the bowls, which were then filled with the lead-silver alloy (con-

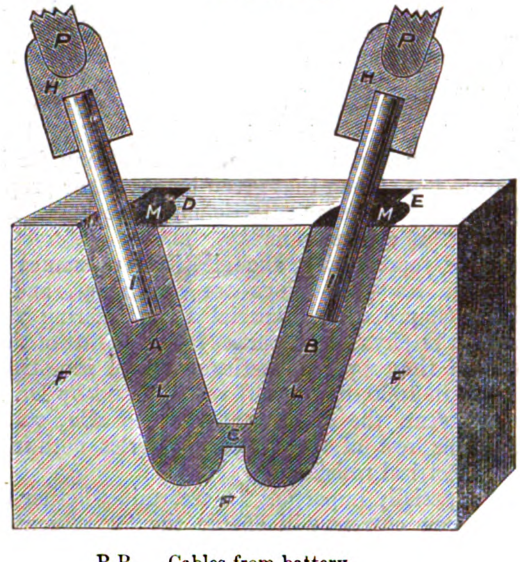
Digitized by Google

taining 2 per cent. of silver) by placing them in a bath of the fused alloy and allowing the metal to enter the bowls through the stems. A current from the forty-cell battery was then passed for twenty minutes, when both bowls were rapidly withdrawn. The contents proved on assay to be identical in composition. The ends of the stems while in the bath were about five millimetres apart.

The nature of the subsequent experiments is best shown by the sections of the firebrick receptacles submitted to the committee and by the following diagram :—

Scale one half.



P P, Cables from battery.
H H, Copper holders.
M M, Cavity for withdrawal of sample.
I I, Wrought-iron rods.
F F F, Soft fire brick.
L L, Silver-lead or gold-lead alloy.

The secondary batteries used for the electric lighting of the Mint were placed at my disposal by Mr. R. A. Hill, the superintendent of the Operative Department, to whose assistance I am much indebted. The weight of the alloy used in the experiments was about 500 grammes.

TABLE A.

Samples.	Time from starting current.	Weight in grammes of Gold obtained from two grammes of the Alloy. Positive Side.	Negative Side.
1	0′	(1) 0·04022 (2) 0·04007	(1) 0·03905 (2) 0 03855
2	10′	(1) 0·04029 highest (2) 0·04026	(1) 0·03954 (2) 0·03920 lowest
3	23′	(1) 0·03988 (2) 0·03973	(1) 0 03944 (2) 0·04010
4	40′	(1) 0·03980 (2) 0·03966	(1) 0·04009 (2) 0·04010
	Totals	0·23962	0·23847*
5	45′	(1) 0·03917 (2) 0·04016	(1) 0·03926 (2) 0·04051

* Total difference + 0·00115 grm.

With the appliance arranged, as shown in the diagram, the momentary application of twelve cells (supplied by the Electrical Storage Company) projected the metal (a 5 per cent. lead-silver alloy) from the firebrick receptacle, while ten cells rapidly heated the iron terminals to redness and fused the lead "lugs" of the cells. It was not found practicable to employ more than four cells for any experiment which lasted more than a few minutes, and in no case did the strength of the current exceed 300 amperes.

The following experiment with a gold-lead alloy containing about 2 per cent. of gold is given as showing the method of working :—Before melting the alloy two grammes yielded on assay 0·03981 gramme (or 1·99 per cent.) of gold ; after the fusion had taken place the samples taken gave on assay the results shown in Table A. They were withdrawn from the cavities marked M, M, on the diagram at the periods indicated in the table. The current used was from three of the secondary cells connected in series.

For the purpose of controlling the results, samples 1 and 5 were taken from the molten metal while no current was passing, and were assayed with the rest. It will be seen from the above table that the difference varied from a minimum of one ten-thousandth as deduced from the total difference found on assaying samples 2 to 4, to a maximum of five ten-thousandth presented by sample 2. The alloys of lead with 2 per cent. of silver and with 51 per cent. of silver also gave negative results, and experiments as a whole, so far as they have yet been carried, tend to show that an alloy conducts metallically, and that its constituents cannot be separated by an intense electric current. The experiments, however, can only be considered to be preliminary. They must be repeated and extended, and alloys of which arsenic is a constituent must be tried ; and further, it is specially important to examine the behaviour of such alloys as those of tin-copper and bismuth-gold, as certain members of both series show marked points on the curves representing the electrical resistance which would appear to indicate the existence of definite compounds.

DISCUSSION.

Dr. GLADSTONE said that the suggestion that this experiment could be made better by means of a change of resistance attributed to him by Prof. Austen really emanated from Mr. Hibbert, the speaker's assistant. Mr. Hibbert had recently been making experiments by employing fusible metal which melted under 100 degrees of temperature, with a result similar to that brought under the notice of the section by Prof. Austen—that was to say absolutely *nil.* There seemed to be no transference whatever of the metal from one point to the other. He and Mr. Hibbert agreed that the investigations had been carried far enough to warrant them in saying that the result was a negative one.

Prof. S. P. THOMPSON : I wish to ask Prof. Wiedemann whether the alloys used in his experiments belonged to that class of alloys the formation of which is accompanied by an evolution of heat or not.

Prof. WIEDEMANN : I think not.

Sir WM. THOMSON : I think that the paper of Prof. Austen speaks for itself. The expressions of opinion that Dr. Gladstone and Prof. Wiedemann have given confirm the result, and I think that this discovery has been quite settled and made known to the world to-day for the first time. It is a most valuable and important contribution to our knowledge on the subject.

BERNARDO'S METHOD OF ELECTRIC WELDING.*

BY DR. R. RÜHLMANN.

When the author first saw Dr. Bernardo's method in use at St. Petersburg he was involuntarily reminded of Columbus and the egg. It has been well known for many years that almost all substances were readily fusible in the electric arc, and Siemens, Wallner, Cowles, and others have done much work in the direction of electrical welding by this means, with more or less success. The principal point in which Bernardo differs from his predecessors is that he makes the metal to be welded *itself the negative pole*, the positive being a carbon rod. The strong reducing action thus brought to bear on the metal keeps it perfectly clean and unoxidised. If the poles are reversed the fluid metal is promptly covered with a layer of oxide, which makes the welding almost impossible, and there is also great danger of burning holes. Bernardo uses as a source of current seven sets of accumulators in parallel, each set 70 cells in series. These he charges continually while

* *Elektrotechnische Zeitschrift*, November, 1887.

Digitized by Google

working by a shunt dynamo giving 120 amperes at 175 volts. He uses special battery plates made of lead strip, as he has found that "pasted" cells will not stand the very heavy charge and discharge currents he employs. Messrs. Rothschild had great trouble at Creil from using "pasted" plates.

The E.M.F. and current required depend on the size, &c., of the work to be done. As an example, to weld together two pieces of ⅜in. boiler plate, 40 cells in series and three in parallel would be taken, one end joined to the plates, and the other by a flexible lead to a 1in. carbon rod in a portable holder. The metal is then touched with the rod, which is immediately withdrawn from a quarter to half an inch, thus striking an arc. The metal at the point where the arc forms melts immediately, like so much wax, and runs perfectly fluid. Through the dark spectacles the arc appears like a blow-pipe flame, and is manipulated much as if it were one. If the effect is too strong, and the metal boils and evaporates, fewer cells in parallel are used; if the arc goes out too often more are added in series.

If heavy pieces of metal of high melting point are to be joined, large currents and E.M.F. must be used, the carbons being proportionately larger, and *vice versâ*. The action of the arc is, like that of a blow-pipe flame, very local; only that part of the metal which requires to be melted is much heated, and the moment the arc is removed the fluid metal solidifies.

The most refractory metals are instantly liquefied, and the work can be done with great rapidity.

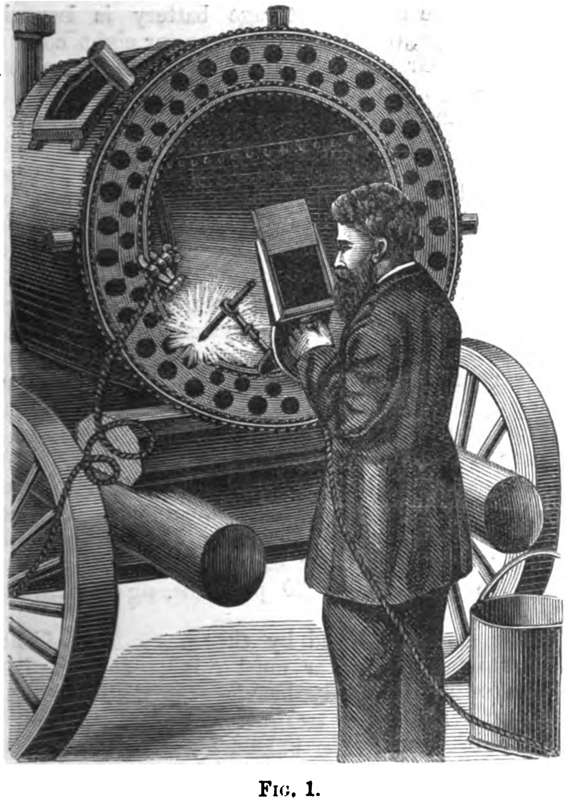


Fig. 1.

The metals to be operated on require hardly any previous preparation, as with the high E.M.F. and currents used even a heavy coating of rust is at once fused. A little sand is used to unite with any oxide not reduced, and the slag thus formed protects the finished part from the oxygen of the air while cooling.

It is a great advantage in Bernardo's method over ordinary welding that the heat can be so easily taken to the place required, instead of having to bring the metal to the forge. Fig. 1 is from a photograph taken when repairing a boiler, and is a good example of the extreme simplicity and convenience of the method. The negative lead is attached to any part of the boiler by the small vice on the left, and then by taking the positive carbon-holder in the hand any part of the boiler can be operated on.

Besides welding two pieces of steel, wrought or cast iron, &c., together, the process has been used to join iron with copper, tin, zinc, brass, lead, steel, or cast iron with perfect success, as also to weld copper and brass, brass and brass, &c., and to *coat* iron with copper, tin, and lead. It may also be used to cut up as well as join a piece of iron plate, &c., as the melted metal runs off like water if no means are taken to retain it; and it may be noted that the process may even be used *under water* both for welding and for cutting metals.

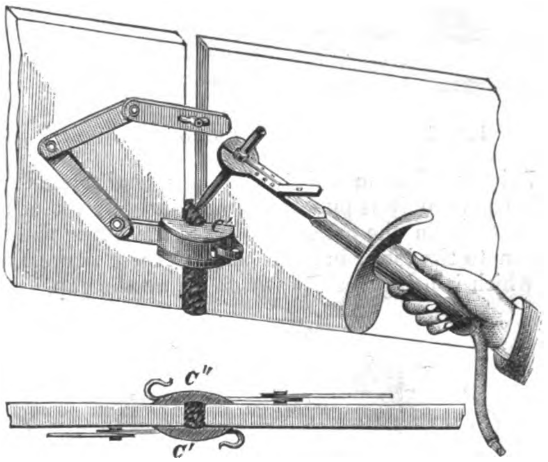

Fig. 2.

Since the action is so rapid, and the metal so quickly cooled after welding by conduction to the surrounding parts, there is no time for any appreciable chemical action to take place, as the following analysis shows:—

—	Steel.		Iron.	
	Unworked.	Melted.	Unworked.	Melted.
Iron	98·86	99·39	98·90	99·43
Carbon	·48	·25	·34	·14
Silicium	·04	Traces	Traces	Traces
Manganese	·5	·25	·50	·23
Sulphur	·04	·04	·14	·09
Phosphorus	·08	·07	·12	·11
	100·00	100·00	100·00	100·00

The "melted" columns are analyses of pieces obtained by allowing the fluid metal to run off under the arc instead of retaining it in place. A further advantage of joining metals electrically is that nothing of the nature of a solder with different chemical and physical properties to the metals treated is employed, and that the joint is extremely little if at all weaker than the original unworked metal.

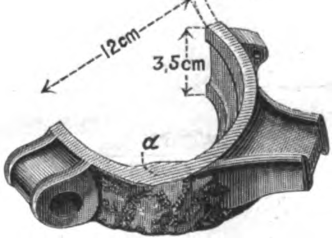

Fig. 3.

Fig. 2 shows the method used for joining two upright plates. C′ C″ are carbon blocks to keep the fluid metal in, and are shifted up from time to time as the joint is made.

Fig. 3 is a cast iron excentric strap, which was broken with a hammer at *a*, and then mended by fusing it together with

Digitized by Google

small pieces of rolled iron, a little sand being used as flux. The joint is perfect, and neither hard nor brittle.

Figs. 4 and 5 show butt and lap joints, and Fig. 6 a pair of plates in process of being electrically riveted.

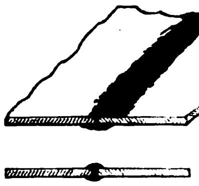

Fig. 4.

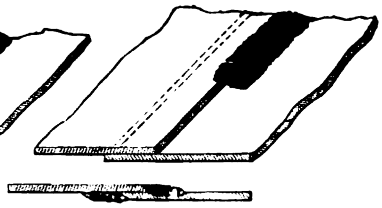

Fig. 5.

Fig. 7 shows what may be called a "semi-riveted" joint. The upper plate only is punched, and a sort of rivet of molten metal built up in the hole, the edge of the upper plate being welded on to the lower in addition (*f* in these figures) a piece of iron which is being fused down to fill up the gap.

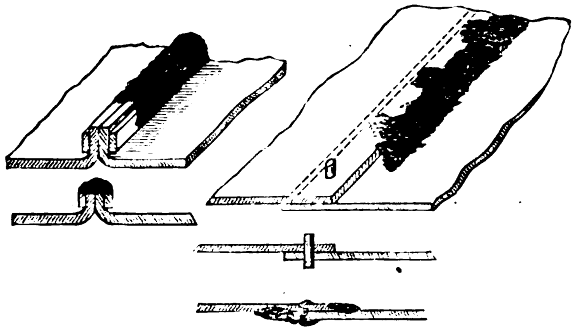

Fig. 6.

Fig. 8 shows two pieces of a thick iron rod being joined, a carbon block *b* being used to retain the molten metal.

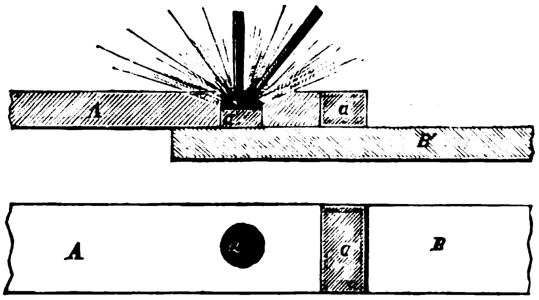

Fig. 7.

Among other uses may be mentioned that of welding fine steel on to a cast iron body for tools, &c., without any risk of

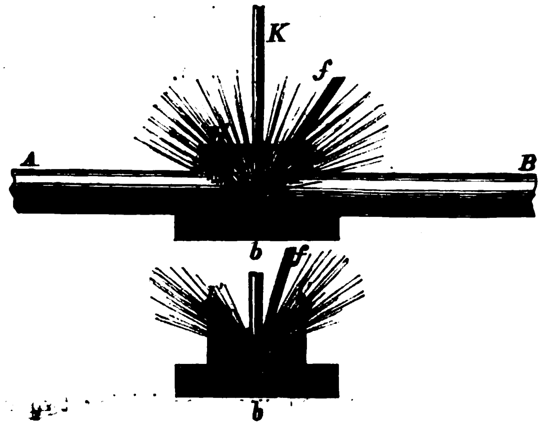

Fig. 8.

the steel being burnt, and for filling up blow holes which may only have been discovered after a considerable amount of work has been done on a piece of metal.

THE ARGUMENT AGAINST STORAGE BATTERIES FOR ELECTRIC TRACTION.*

The Bentley-Knight Electric Railway Company begs to submit its criticism upon the use of the storage battery for street railway purposes.

No idea could be more attractive than that of a self-propelled car, carrying within itself its own energy—independent of any connection with line wires—and dispensing with expensive conduits and unsightly elevated conductors. On the advent of an apparently practicable storage battery, in 1881, all these advantages were claimed for it. It shortly demonstrated its utter worthlessness as an adjunct to commercial electric lighting, but its promoters claimed that it possessed a peculiar fitness for tramway use. It has been paraded through every city of Europe, and has, to judge from Press comments and *ex parte* statements, never failed to make most successful and startling exhibitions. The boom has now reached this country, and New York, Philadelphia, and Boston have each been favoured by the attention of the several inventors and their exploiting companies. Since the European experiments of 1882 little or no material progress has been made in the practical use of the storage battery for street car purposes, and it is our belief, based on most careful investigation, that its radical structural difficulties cannot be overcome. It would be profitless to discuss them here; nor will we dispute the allegations as to weight, efficiency, &c., which the enthusiastic promoters make.

We will assume that the storage battery is beyond the experimental stage, capable of driving a car eight hours without recharging. Granting the most favourable premises, we will make a short practical comparison between the storage and direct systems, both as to operating expenses and first cost. We will also assume that a set of street car batteries will weigh 3,200lb., that they will give a return of 65 per cent. of the electrical energy expended in charging, that a set which will run eight hours can be charged in ten hours, and that a set will run 12,500 miles without renewal of the batteries or extensive repairs.

1st. Cost of Operation.—Two great losses are chargeable against the economy of the storage system, viz.:—Loss in conversion of energy in the battery and the additional weight carried on the car. In the direct system, electricity from the generating dynamo is transmitted to the motor on the car by the line conductors. In the storage system, electricity from the dynamo is used to charge the batteries, which, in turn, supply the motor. In the latter system the loss is conceded to be 35 per cent. In the former system, it is a matter of simple arithmetical calculation to make the loss inappreciable. It should never exceed 5 per cent., however long the line. This leaves a difference of 30 per cent. against the storage system.

A greater loss is entailed by the heavy load of batteries which the storage system car must carry. It necessitates a heavier car construction and a heavier motor, all of which adds to the weight. In practice two motors are often used. The additional weight entailed by the storage system easily reaches 4,000lb. per car. The motor and driving mechanism for a car run under the direct system weighs 1,600lb. The equipment where batteries are used is necessarily heavier on account of the added battery weight to be moved, but we will keep the same figure for both. A car weighs nearly 5,000lb. In Boston (1886), the average number of passengers per car mile was 10, so that the average load may be put at 1,400lb. We then have the following summary:—

	Storage system.	Direct system.
Car	5,000lb.	5,000lb.
Motor, &c.	1,600lb.	1,600lb.
Passengers	1,400lb.	1,400lb.
Batteries, &c.	4,000lb.	——
	12,000lb.	8,000lb.

* *An ex parte statement read before the American Street Railway Convention at Philadelphia by the representative of the Bentley-Knight Electric Railway (Conduit System).*

Digitized by Google

That is, 50 per cent. more power must be expended to propel the storage car, and 30 per cent more power to overcome the loss of conversion in the batteries, making a total of 80 per cent. greater cost for power than the direct system. This means not only 80 per cent. more coal consumed but 80 per cent. added to the size and cost of the steam and dynamo plant in the generating station.

There are additional losses in the storage system which are less easy to compute, but which are hardly less serious than those mentioned. Twelve thousand five hundred miles are given as the life of a battery. Now, 100 miles per day is not an excessive mileage for an electric car, so that the battery must be renewed, wholly or in part, every 125 days, or three times per year. What this would cost it is impossible to say, but it is plainly a serious item. On the other hand, the depreciation of an overhead wire, or a conduit, is very slight, not more than 3 or 4 per cent. per annum. The handling of storage batteries is also a very considerable item. To transfer 3,200lb. into and out of a car two or three times a day is not a slight matter, while the shifting and removal necessary to a large plant must be added to it. None but skilled labour could be employed in handling, recharging, and taking care of the batteries. That has been conclusively proved.

2nd. First Cost of the Storage System.—There is little reliable data on this point, but putting a very moderate estimate upon it, it far exceeds that of the most expensive direct system. There should be at least three sets of batteries for each car—a considerable increase in the motor capacity—80 per cent. more dynamo and steam plant in the generating station, and twice the floor space, since each car must have a stand for charged and discharged batteries. This could not cost less than $2,500 per car, which is to be balanced against the conduit and line conductors of the direct system. The cost of the latter varies, of course, with the number of cars per mile. Taking a well-known road in Boston, however, which has 700 cars and 70 miles of track, there are 10 cars per mile, which, equipped with conduit and conductors at $4 per foot, would cost $2,000 per car. As a matter of fact, one-fourth of this mileage could be equipped with overhead wire at $2,500 per mile, which would bring the cost to $1,650 per car.

An important fact, which we have left out of this computation, is that most existing roads must be equipped with new and heavier track to fit them for the weight of storage cars. The present rails will stand an addition of 1,600lb. to each car, but not an addition of 5,600lb. (The most widely advertised storage car run in this country weighs over 6½ tons.) These facts are plain and simple, and in view of them it is difficult to see how the introduction of the storage system can be seriously contemplated when conduit and elevated conductor roads on the direct system are feasible. As we have said before, the superficial appearance of the storage battery for street cars is very attractive. It is a simple electrical problem to charge a battery and run a car for an occasional trip. A boat equipped with a battery has crossed the English Channel, while for lighting railway trains, where weight and expense are no object, and the work easy and constant, it has a certain value; but for practical street car work it has just enough promise to make it a dangerous and insidious deceit. The storage power, however, is a disease which users of electricity must go through as a child has the measles. The electric lighting interests went through it some years ago at an enormous expense, and to-day not one of the large electric lighting companies is supporting the storage battery. If this paper, hurriedly written and far from complete, will in any degree mitigate the malady to the street railway interests, it will have attained its end.

A German Central Lighting Station Tariff.—The central station at Mailand is now supplying current by meter on the following sliding scale:—Up to 40 hours 12 centimes per ampere (say 1·2d.), 6 centimes per 10 candle-power lamp, 9 centimes per 16 candle-power lamp, falling to 11, 10, 9, 8, and 7·5 centimes per ampere, according as the consumption increases to 80, 100, 125, or 150 or more hours, with proportionate charges for 10 and 16 candle-power lamps. The rent of meters is: 50-lamp, 5s.; 50 to 100, 7s. 6d.; over 100, 10s.

REVIEWS.

Recent Advances in Electricity, Electric Lighting, Magnetism, Telegraphy, Telephony, &c., &c. Edited by Henry Greer, New York College of Electrical Engineering.

Amongst the phraseology of polite literature we are unable to find any available form of expression which contains the full and precise analogue of the colloquial term "cool cheek." We wish there were some such phrase. In default, we are driven at times to the use of some provokingly mild and common-place expression—such, for instance, as "singular." In what follows, however, if we should make use of this milder form, our readers may, if they please, read into it the meaning hinted at above. They will presently agree with us that never was a more vigorous expression more loudly called for.

This book contains an abstract of Edison's recent paper on the pyro-magnetic dynamo, a reprint of an article on "Phelp's Induction Telegraph," a feeble chapter on navigating balloons by electricity, and a large number of extracts from newspaper articles, antiquated patent specifications, prospectuses of joint-stock companies and out-of-date scientific papers, all of which are concerned with various kinds of storage batteries. Considering that this last subject occupies three-fourths of the book, *while the information is in no case brought down to a later date than the summer of 1883*, we venture to think it decidedly *singular* that the work should be entitled "Recent Advances in Electricity." But the lower part of the title page is even more singular than the top. We are informed thereon that the work includes "articles by Editor of *Electrician* of London (*sic*), Prof. Thomson of London, and Prof. Edison." The words "of London" had been scratched out with a knife on the outer cover of the copy which reached our hands, but there happened to be an inner title page which had not received the same careful attention. Under almost any other circumstances we need scarcely say that we should feel gratified at thus being connected with "Prof. Edison" and "Prof. Thomson of London" (although we hear for the first time of the latter gentleman); but we are free to confess that when this honour involves also that of being "edited" by Mr. Greer, we do not take it as a compliment. Our four-year-old article on "Storage Batteries" was doubtless highly useful and instructive when it first appeared, but we regretfully admit that we are not entitled to claim for it a permanent place in the literature of science, certainly not under the title which Mr. Greer has chosen to give it. As for Prof. Thomson, he has been even more cruelly treated. Mr. Greer has evidently attempted to "abstract" him (in more senses than one). The following is a specimen of the result:—"As this was one point of Dr. G.'s *(sic.)* explanation, both he and Mr. Tribe, who has always shared Dr. G.'s researches in this field, and Prof. Lodge repeated their experiments, and *Nature* had communications from the two gentlemen, which (*sic*) both adhered to their former opinions."

Perhaps the most singular fact of all is that this volume is priced at four shillings.

THE PROGRESS OF THE THOMSON-HOUSTON SYSTEM.

The story of the "rise and progress" of the Thomson-Houston system of electric lighting is beyond question one of the most remarkable in the annals of applied science. It is difficult to realise that it is now little more than four years ago that this system was first heard of, and some time elapsed, even in America, before it began to attract any great attention. In this country the interest first aroused was due to the difficulty of grasping the exact method of working of the machine, and to this day great is the tribulation of students who strive to master its cycle of operations. Notwithstanding these features the system came rapidly to the front, and we learn that at the present moment the parent company in America are behindhand in the execution of orders to the extent of some 4,500 arc lamps and apparatus, 15,000 incandescent lamps and fittings, and a corresponding number of dynamo machines. By the end of this year it is expected that the total number of these arc lamps installed in America will reach the enormous total of 50,000; while the

Digitized by Google

number of central stations working this system will at least reach 300, if it does not exceed that figure. The incandescent lamp has been by no means neglected by this company, and in our issue of March 18th, 1887, we illustrated and described the arrangement by which lamps of low resistance are run in simple series upon the arc lamp circuits. These lamps are made in various sizes, giving from 16 candle-power to 125 candle-power. In addition to this method, "distributors" are employed, which enable any type of lamp to be run in multiple series on constant current circuits. That these systems are thoroughly practical may be judged from the fact that already some thousands of incandescents are at work on these conditions.

The distribution of power by means of motors adapted to work in series with constant current is also rapidly becoming an important feature of the central station business. The value of an addition which enables the plant to earn revenue by day as well as night cannot easily be over-estimated. The average earnings of the American local companies have enabled dividends of from 8 per cent. to 16 per cent. to be paid upon arc lamps alone, so that with the further sources of revenue which have been named, their financial prospects may be held to be of a solid character.

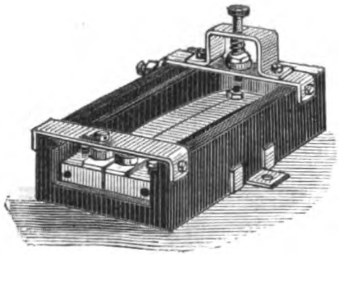
The most important event in the recent history of the company has been the signing of a working agreement with the Westinghouse Company, whereby the former becomes entitled to employ the alternating system for long-distance distribution, while the latter will make exclusive use of the Thomson-Houston arc lamp. In the hands of Prof. Elihu Thomson the transformer system may well be expected to undergo new development.

At present the business which is chiefly engaging the attention of the experimental staff of the company is the production of an arc lamp of lower candle-power than the 1,200 candle-power and 1,000 candle-power lamps which have hitherto been made. A lamp of 800 candle-power will shortly be ready for issue, though we may anticipate that the movement in this direction will not stop at that point.

In conclusion, we may remark that it is impossible to avoid the recognition of the remarkable nature of the success that has followed this company's operations, and though we could wish that they and the scene of their labours had been on this side of the Atlantic, we none the less warmly congratulate the representatives of the Thomson-Houston Company on the unqualified success of the system.

"EXCESS" ALARMS FOR SECONDARY BATTERIES.

We illustrate herewith a simple form of alarm which is intended to be used with secondary batteries when either the charging or discharging current exceeds the proper limit. This alarm has been designed by Messrs. Drake and Gorham, in conjunction with the United Electrical Engineering Company, and is manufactured by the latter. The apparatus is so arranged that whenever the current exceeds the proper limit an electric bell comes into circuit and continues ringing until the normal conditions of working are restored.



The principle adopted is that of the thermic alarms, which depend for their action upon the bending of a compound metallic plate under variations of temperature. In this case a strip or plate, consisting of two metals rolled or soldered together, has a narrow slit cut in it almost, but not quite, from end to end, thus forming a narrow flat U-piece, the ends of which are rigidly held and connected to terminals, which are placed in the main circuit. The closed end of the loop is free to move, and carries a carbon stud. Immediately opposed to this is a similar stud, to be connected through an ordinary electric bell to one of the cells in such a manner that when the two studs make contact the current from one cell only will pass through the coil of the bell. The distance between the two contacts is adjustable.

The tendency of the current in passing round the loop is to cause the free parts carrying the contact stud to bend upward, and should the pre-arranged limit be exceeded alarm is immediately given by the bell, which may be fixed at a distance if required. The alarm is found to be practically constant and reliable, variations in the temperature of the atmosphere being inappreciable in effect.

The usefulness of these thermic alarms is not, of course, confined to accumulator work, as they may be employed in connection with any arrangement of circuits the current in which needs to be controlled.

Cut-outs and other forms of control have been designed on the same principle (which certainly lends itself to economy in manufacture), and will, we understand, be shortly introduced.

CORRESPONDENCE.

DEEP-SEA CABLE SOUNDINGS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I cannot quite agree with you in your criticism on Mr. Stallibrass's very able paper on "Deep-Sea Soundings," where you say in your last week's "Notes," that he "rather overdid his advocacy of preliminary surveys for cable operations," and inasmuch as in the same column you refer to my remarks in the discussion on the subject, I think it as well to express my dissent. On the contrary, I most cordially agree with Mr. Stallibrass in the matter. All that I have ventured to submit was that he would, perhaps, have actually strengthened his point if he had mentioned the arguments (however little weight they may carry) on the other side of the question (if only on principle), and to some extent balanced the one against the other. This, in my opinion, Mr. Stallibrass could well have afforded to do.

I then alluded to the arguments adverse to such preliminary soundings, at the same time expressing an opinion that under certain circumstances they were very possibly impracticable owing to lack of time, or, indeed (in the earlier days), through scarcity of money; and that, therefore, it would be, perhaps, inexpedient to blame instances where similar preliminary surveys had not been effected. We should, I think, remember that it is only by these somewhat dearly bought practical experiences that we have learnt the absolute necessity of such surveys, and discovered that soundings at distances of 30 miles apart are no guide as to the configuration of the bottom, and, moreover, afford only a rough estimate of slack cable requirements.

Again, often through no fault of theirs, contractors are frequently compelled to lay a cable by a certain date, those by whom it is ordered being constantly, even nowadays, ignorant of the value of preliminary surveys.

It seems to me that a big allowance should also be made to early submarine telegraphy for the very altered circumstances brought about by the practical introduction of pianoforte steel sounding wire as being especially adapted to our work. My remarks were merely intended as a humble, and possibly useful, addition to Mr. Stallibrass's very able paper, from a business point of view.—Yours, &c.,

CHARLES BRIGHT, JUN.

THE TEACHING OF ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your review of Mr. Larden's new text-book touches on the best order of treatment of electrical and magnetic subjects. That this should be very connected and lead the student step by step there cannot be two opinions. My own view is that this end is not secured when the text-book is an historical compendium, subjects being treated in their historical order, or when large demands are made on a student's imagination in pursuing some physical theory. Experience in dealing with students has led me to the firm conviction that the study of the simple electrical circuit, electrical units of measurement and measuring instruments are the most easily comprehended to start with. By measurement abstract ideas are reduced to the practical.

The recent works by Prof. Ayrton and Profs. Stewart and Gee are distinct innovations on the old historical and general style, and their practical value to the student is widely felt.

Digitized by Google

The subject of electrostatics is a growingly important one in connection with alternating currents, but owing to the fact that measurements are less easily made than in electro-dynamics and magnetism, it seems more desirable that the *entrée* to the study should be through the latter subjects.—Yours, &c.,

H. D. WILKINSON.

School Electrical Engineering, 12, Princes-street, Hanover-square, W.

PRIMARY BATTERIES: A CHALLENGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I be allowed to trespass on your valuable space in reference to those bugbears, primary batteries, as one most interested in the Holmes-Burke type?

There are several installations of modified type of above (the improvements of your humble servant), and the latest construction under my patent will, I trust, be of service, both for lighting, telegraphic, and mining purposes. It is not my intention to raise a company, or ask any one for a penny. The chief cost of working these primary batteries is not the labour, but consumption of materials.

I challenge any primary battery inventor or maker to the following trial, but the plates used must not be prepared electrolytically—as I look upon such as accumulators or secondary batteries—and the cells must be of similar size and number to mine. The battery shall be prepared and allowed to run a given number of Swan-Edison lamps of a given E.M.F. and candle-power. The runs shall extend over fourteen days or more; the time occupied in labour shall be carefully noted, also consumption of materials. If my battery fails as against others I will consent to pay £25 to any deserving charity, or I will present it to the Chemical Society or Telegraph-Engineers to purchase the successful battery for future experiments in their lecture rooms. I of course debar colourable imitations of my battery from competition. The arbitrator must be an electrician and chemist of reputation, and not pecuniarily interested in any battery system.

I also intend to submit a certain number of cells for trial as to their suitability for telegraphic or mining purposes, but as this would mean leaving them when charged with acids, &c., for at least six months, it would naturally have to be in connection with some telegraph company.—Yours, &c.,

WILLIAM WEBSTER, JUN., F.C.S., A.S.T.E.

6, Great St. Helens, E.C., 23rd Nov., 1887.

PUMPING BY ELECTRICITY IN COAL MINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have been very much interested in reading a brief description, in your last week's issue, of the electrical pumping plant at Messrs. Locke's collieries, Normanton, which appears to be doing good work. We have working at these collieries what I believe to be the largest pumping plant at present driven by electricity. A pump delivering 114 gallons per minute through a head of 300 feet = 10·36 horse-power is placed more than a mile underground, and is doing excellent work. This is the third pump so working here, the first having been started more than four years ago.—Yours, &c.

FRANK BRAIN.

Trafalgar Collieries, Forest of Dean, 21st November, 1887.

SPRINGS ON TELEGRAPH WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: To prevent misconception on the part of any of your readers who may be disposed, from the illustrations published in your journal, pages 504 and 538, to judge that the "bow" and the "automatic insulating grippers" are the only features distinguishing my arrangement from that of M. Bardonnaut, it becomes necessary for me to state that within the helix of my springs is a further improvement in the shape of a simple automatic *restrainer*, which causes my regulator to withold its relief from the line wire until the stress has reached nearly one-half its breaking intensity, when my regulator begins to dispense its relief to the wire in so economical a manner as to always reserve for abnormal storms its full power of extensibility.—Yours, &c.,

FRANK CAWS.

Sunderland, 16th November, 1887.

ON TRADE DISCOUNTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If I am not overstepping the bounds of the courtesies of scientific journalism I should like to enter an earnest protest against the absurdity, as it seems to me, of dragging mathematical calculations, such as those given by Mr. Money-Kent in your current number, into a simple commercial transaction that any educated boy should be able to manipulate without the assistance of either pen or paper. Practical business men avoid long mathematical calculations in their every day transactions, not always because they are incapable of making them, but because they know how easy it is to make a slip in the middle, which will put the result wrong.

Mr. Money-Kent is in error in supposing that practical business men adopt a happy-go-lucky method of making their calculations; they do nothing of the kind, but they adopt simple rules that cannot easily be mistaken nor lead them into error.

I venture to give one for the benefit of your readers dealing with the case in point, and I would ask your readers to judge which rule they would prefer using.

My rule is as follows:—

Find the vulgar fraction corresponding to the discount to be allowed, and substract from its denominator a sum equal to the numerator; the result is the fraction required. Thus, 5 per cent. = $\frac{1}{20}$, requires $\frac{1}{19}$; 10 per cent. = $\frac{1}{10}$, requires $\frac{1}{9}$; 15 per cent. = $\frac{3}{20}$, requires $\frac{3}{17}$; &c., &c. It will be seen that it works to exactly the same figures as Mr. Money-Kent's *simple* formula; but I venture to think that whereas almost any educated boy of intelligence could run out the figures required in ordinary use in his head on my plan, a great many would be puzzled by Mr. Money-Kent's, particularly if preceded by the formidable calculation given.

If Mr. Money-Kent has a fancy for showing everything by means of curves, there is nothing to prevent him drawing a curve on my plan, after calculating a certain number of the principal discounts; but I would suggest as a better plan that he should let his office boy calculate the actual figures for each discount that he is likely to use and enter them in a table, which may be posted on a card and hung up in the office. I fancy there would be less liability to error on this plan always.—Yours, &c.,

SYDNEY F. WALKER.

195, Severn-road, Cardiff, November 15th, 1887.

THE COST OF ELECTRIC LIGHT FITTINGS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is refreshing to be told that "there is no need to go into the cost of silk-covered wire" (*see* "Mr. Haxell's letter to the *Daily News*," page 27, last week's *Electrician*). Will you be good enough to inform me if it is usual for respectable contractors to wire a house with the omnipotent "silk-covered" wire?—Yours, &c.

MECHANIC.

SOCIETY OF ARTS.

PROF. S. P. THOMPSON ON MERCURIAL AIR PUMPS.

At the Society of Arts, on Wednesday last, Prof. S. P. THOMPSON read a most interesting paper on "The History and Development of the Mercury Air Pump." It was doubtless a surprise to many of his audience to see in one of his diagrams the sketch of a pump made by Swedenborg in 1722, which was, though rude in form, exactly the same in principle as the well-known Geissler pump. Various improvements were successively introduced by Baader,

Digitized by Google

Hindenburg, Edelcrantz up to 1855, when Dr. Geissler brought out a pump which may be considered as the first modern practical form. The next great stride was made in 1865, when Dr. Sprengel brought out his well-known pump with mercury dropping down a fall tube. Several modern improvements were described, including Mr. Swinburne's pump and a very simple valve by Meisens, also an ingenious rotating pump. The advantages of short falls and of exhaust into a partial vacuum instead of into the air were dwelt upon, and the well-known M'Cleod gauge described. Prof. Thompson concluded by pointing out that, as was so often the case with important types of apparatus, the mercurial pumps could hardly be said to be invented at all, but to have grown out of the combined efforts of a large number of workers.

In the discussion which followed, Prof. Crookes, after saying that his idea of a good vacuum had been continuously enlarging from that obtained by the ordinary mechanical pump to that now obtained by the most modern mercury pumps, pointed out that even in a vacuum of one-hundredth of one-millionth of an atmosphere, which might be expressed as $\frac{1}{10}$in. on a barometric column 200 miles high, there were some 10 billion molecules still left in each cubic centimetre, so that even at that degree of exhaustion we were at an almost hopeless distance from a true vacuum.

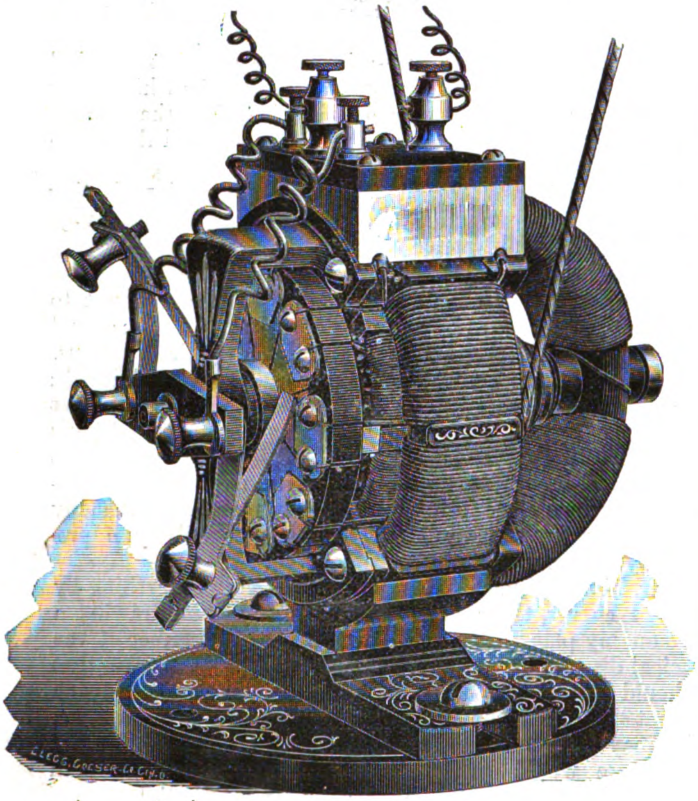


Fig. 1.—The Card Motor.

Mr. Swinburne differed from Prof. Thompson as to the use of the short pump, on the ground of difficulty in maintaining the partial vacuum into which the falls exhausted. He pointed out that the readings of the M'Cleod gauge were rendered doubtful owing to mercury having a perceptible vapour tension.

Dr. Ramsay thought that the gauge might also give false readings owing to the air sticking to the sides of the tube instead of all going to the top. He stated that to the best of his remembrance from some of his own experiments, he had found vapour tension of mercury to be about 2×10^{-7} atmospheres.

Mr. Boys said that when working with a Sprengel pump heated too hot to touch, he had noticed that the mercury appeared to be in far more intimate contact with the fall tubes, owing probably to the air being driven off them by the heat, and that the hammering of the falling drops of mercury was very much louder.

Mr. Mordey, as a proof of the excellence of a paraffin joint, mentioned that he had had a barometer tube sealed at the top with it, which had kept its Torricellian vacuum for the last nine years.

In his reply, Prof. Thompson said that one very great advantage of the short pump over the long one was that the mercury was never in contact with air except at a low pressure, and that consequently less air attached itself to its surface.

A cordial vote of thanks was given to Prof. Thompson for his interesting paper.

THE CARD ELECTRIC MOTOR.

The small electric motor illustrated in the adjoining figures hails from the United States, and is made by the G. F. Card Manufacturing Company, of Cincinnati. The apparatus measures 6in. by $7\frac{1}{2}$in. by 5in. in height, and weighs 9lb. It is wound in series for a current of $2\frac{1}{2}$ amperes. When used on a constant potential incandescent lamp circuit, a number of small lamps of lower voltage are connected in parallel with the motor, and a switch is arranged to regulate the speed of the armature by cutting these lamps out in succession. The circuit is broken before the last lamp is cut out.

The armature is shown in Fig. 2. The following description of its merits is furnished us by the makers :—" All the sections can be taken out and replaced without disturbing a wire; consequently, when the sections are worn on one face they can in a few minutes be reversed, so as to get the greatest wear out of the metal, or, if worn on both faces, new sections can be substituted. As can be seen by the figure, an observation can be taken on both brushes at the same time, to ascertain whether the current is being wasted by sparking, a convenience which will be appreciated by those having machines to look after. An experience of nearly a year in the use of a dynamo of considerable size, fitted with this form of commutator, enables the inventor to state that the differential wear, which at once suggests itself as an objection to such a device, is an entirely negligible matter."

PRIMARY BATTERIES FOR ILLUMINATING PURPOSES.

(Concluded from page 38.)

The Eclipse Battery.

The Eclipse primary battery, which is the invention of Mr. Henry I. Harris, was brought out in June last. It is a portable battery, and consists of a series of cells made of vulcanite, and filled with a solution

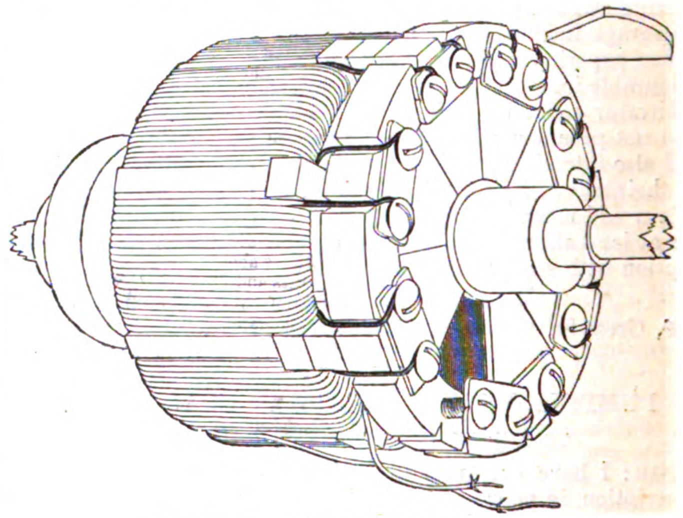

Fig. 2.—Armature of the Card Motor.

of sulphuric acid, in which is a plate of zinc as a positive. Within the vulcanite cell is a porous cell, charged with a solution of nitrate of soda, and in which is the negative element—a carbon pencil. A $2\frac{1}{2}$ candle-power glow lamp for twelve hours is said to cost 1d. The Eclipse battery is said to be very low in price, and to cost only 2d. to charge, the charge lasting for twenty-four hours. The lamps have also been in satisfactory use on twenty omnibuses belonging to the London Road Car Company for two months.

The Newton Battery.

About the same time that the Eclipse battery was introduced to public notice, the Newton primary battery was also brought out and inspected by the author. Since then the disposition of the elements has been altered by Mr. Charles M. Newton, and sundry other modifications have been introduced by him. In this battery the negative plate is of iron, the positive is zinc, the depolariser a plate of oxide of lead, and the exciting fluid a caustic alkali. Each cell of the original battery consisted of an outer case of iron forming the negative plate of the cell. On the bottom of this the depolarising material was spread. Above the latter was placed a diaphragm of parchment paper turned up at the edges so as to divide the cell into an inner and an outer compartment, and at the top, resting on glass insulators at the four corners of the cell, the zinc positive plate was laid horizontally. The alkaline solution was then poured into both compartments and the cell was ready for use. Binding screws were of course attached to the two plates, and that on the zinc was protected at the surface of the liquid. This battery has been tried and satisfactorily reported upon by Dr. R. M. Walmsley, F.C.S., who stated that a brilliant

Digitized by Google

and steady light was obtainable for 120 hours without attention. He also stated that the local action was practically negligible.

In the improved form of battery which is being brought out by the New Electric Light Syndicate the electrodes are zinc and iron. The cell, which is of iron, contains alternate vertical plates of these metals, the latter having attached to their surfaces the depolarising plates made of oxide of lead. The exciting fluid with which the cell is filled is a solution of caustic alkali. At starting the electromotive force is stated to be 0·69 volt per cell, which, after 130 hours' continuous run at work, only falls to 0·61 volt, and during the same period the current will merely decline about 13 per cent., and is perfectly steady for the first fifty hours. These statements are given on the authority of Dr. Walmsley. When necessary, the battery is recharged, the spent materials being taken away to be regenerated, and the depolarising plates reoxidised while the solution is, by a special process, separated from the dissolved zinc. The solution is reserved for further use, and the zinc is converted into a sulphide for use in paint making.

The chemical action which takes place in the Newton battery has been reported by Mr. Harold Senier, F.C.S., to be as follows:—"The solution of caustic soda gradually dissolves the zinc, forming zinc oxide, which is again dissolved in the solution, and at the same time hydrogen is set free. The free hydrogen is given off from the surface of the iron, and while in the nascent condition robs the lead oxide of its oxygen, with which it forms water, and so prevents the battery polarising. The depolarising action is the only part played by the lead oxide. By this action the litharge is reduced to the form of black sub-oxide, and a portion to the metallic state. The iron is quite unacted upon. The zinc is dissolved to the extent of one-third its original weight. The solution of caustic soda, except that it contains a certain proportion of oxide of zinc in solution appears practically unaltered."

With medium and small installations accumulators are used, and the current is utilised in glow lamps which have been specially designed for the Newton battery. The prime cost of a battery for supplying a current to 50 lamps of 10 candle-power each, with a current of 40 amperes and an E.M.F. of 15 volts, is put at £90. 9s., and its maintenance for 130 hours at £4. 7s.—which is equal to 1s. 9d. per lamp for 130 hours light.

The D'Humy Battery.

The next battery for notice in the order of its appearance before the public is that of Mr. P. R. D'Humy, which was brought out in August last. In this battery, which is known as the Water Primary battery, the positive element is iron in the form of a grid, so that a large surface of metal is exposed within a small compass. The negative element is carbon, and is immersed in nitric acid, the positive element being immersed in water. The cell is divided up into compartments by porous diaphragms, and the acid percolating through the diaphragms permeates and acidulates the water in which the iron electrodes are placed. The installation inspected by the author represents on a small scale a central station, for Mr. D'Humy proposes to apply his system to central lighting. It comprises a battery of 20 cells, each measuring 2ft long by 1ft. wide and 1ft. deep. The battery occupies a floor space of about 11ft. by 5ft., and the current produced is stored in 40 accumulators specially designed by Mr. D'Humy. Each accumulator is about half the size of a cell. This battery is stated to be equal to 35 volts and 40 amperes.

With regard to the cost of maintenance of this battery, according to a report by Messrs. Gooch and Varley, 1 kilogramme (2lb.) of nitric acid consumed in the water battery—and costing, roughly, 4d.—produces a light of 366 candle-power for one hour. One lamp of 10 candle-power, therefore, will cost rather less than half a farthing per hour. For generating the current on the premises Mr. D'Humy has devised a small battery enclosed in a neat cabinet 5ft. high by 3ft. wide and 2ft. deep. The lower portion contains thirty-two cells, the positive element here being a new alloy, invented by Mr. D'Humy. The plates can be raised out of their solutions, and the battery thus kept at rest when light is not required. There is also a simple arrangement for discharging and replenishing the cells. The water battery certainly constitutes a departure in primary battery practice, and by the light of Mr. D'Humy's installation the invention appears to possess points of ingenuity and merit. It has, however, one drawback in the smell emitted by the nitric acid.

The Friedlaender Battery.

A marked improvement has recently been made in the single-fluid bichromate battery by Mr. Albert Friedlaender, of Berlin, who took advantage of the circumstance that chromic acid is now manufactured by a new process at a price at which it can be used for this purpose. Chromic acid can now be purchased for from 9d. to 1s. per lb., whereas it formerly cost from 4s. to 5s. per lb. In the ordinary bi-chromate battery the depolariser is a solution of either bi-chromate of potash or bi-chromate of soda, in which the carbon and the zinc elements are immersed. These batteries are found to clog, owing to the depolariser having a base, but this objection does not exist with chromic acid. Another important advantage is that chromic acid is much more soluble in water than bichromate of potash, and thereby a much more powerful depolariser can be used in a small cell. The Friedlaender battery has several good features in its mechanical arrangement. It is a small battery, and, with a lamp attached to it, forms a useful and convenient portable lamp, one of which is exhibited on the table. It consists of an outer case of ebonite 8in. high by 5in. square in plan. The battery is divided vertically into five cells, and the elements—which are zinc and carbon strips—are arranged in five pairs, and are attached to a small horizontal spindle placed at the back of the battery near the top. One end of this spindle is fitted with a worm-wheel motion, actuated from a thumb screw on the outside. The depolariser is a solution of chromic acid, the acid being supplied as a powder and dissolved in water. The level of the liquid is kept below the spindle to which the elements are attached, and when the battery is not in use these latter are maintained in a horizontal position clear of the solution. To put the battery in action the thumbscrew is turned and the elements are gradually immersed in the depolariser. Two advantages result from this arrangement; in the first place, waste is prevented while the battery is out of action, and in the second, the gradual immersion enables the current to be regulated, and the light graduated and set at any point, from a glimmer to the full capacity of the battery. The zinc and carbon strips are attached to the spindle by set screws, so that the renewal of the zinc can be easily effected in a minute or two. The lamps used are Swan glow lamps of 8 volts by 1 ampere, or between 3 and 4 candle-power. The cells are easily emptied of their spent contents and re-charged with the solution. Each charge costs between 3d. and 4d., and will give a steady current for two and a-half to three lamp hours. The lamp can be attached to the battery either at the front or on the top, or it can be removed and the battery used for surgical or experimental purposes. These batteries are being introduced into this country by the General Electric Apparatus Company previously referred to.

There is, however, another miner's lamp which has also been prominently before the public of late, and this is the Edison and Swan Company's safety lamp. By the kindness of the company, two of these lamps are on the table. The battery here, however, is not a primary but a secondary battery, and the lamp consists of four small accumulators enclosed in a teak box, strengthened with metal bands, and having a small glow lamp mounted on the side of the case and protected by a strong glass. The case is fitted with a hinged lid, secured by a cross bar, fastened with a safety nut, and having a swivel handle. The lamp measures 7in. by 4½in., and it weighs ready for use 6lb. 13oz. The lamp is opened by unscrewing the safety nut and raising the hinged lid, when the battery can be withdrawn. The four cells composing the battery are joined in series, the terminals being brought down the sides of the battery in the form of two contact plates, which, when the battery is put into the case, come in contact with two corresponding plates in the case, and thus convey the current to the lamp. One charge of the battery will last from ten to twelve hours. The battery is recharged from a dynamo machine. With a sufficiently powerful machine several hundreds may be charged at once. The lamp can also be fitted with a fire-damp indicator, which, it is stated, will indicate a percentage of fire-damp or choke-damp as low as one-tenth of 1 per cent.

Conclusions.

The author has now described sixteen primary batteries, being all that have come under his notice, and has given such particulars concerning them as the limitation he has prescribed for the subject will permit. It might be expected that he should now proceed to analyse the various systems, and to pronounce an opinion upon their relative merits. Two things stand in the way of this. In the first place, the present paper has been prepared at short notice, to meet an emergency, and was only commenced three weeks since, so that there has been neither time nor opportunity for such a careful examination to be made as should entitle the conclusions drawn from it to respect. In the next place, the author conceives that no single person should undertake the task of examination. Electric lighting is still but in its infancy, and no system ought to be either condemned or approved without very careful and exhaustive trial. To this end the various batteries should be placed unreservedly in the hands of three disinterested professional men—an electrician, a chemist, and an engineer, for all three professions are represented in every primary battery system. The author is not quite sure that the various patents should not undergo a preliminary investigation by a patent agent. We are, however, fortunate in having among us to-night several eminent electricians, and from these masters of the science, as well as from the inventors of the batteries, we may hope to hear something more respecting the practical value of these batteries than the author has been able to give in his paper. Broadly and generally speaking, it appears to him that it has yet to be proved that any one of the batteries could be applied to the partial illumination of moderate-sized houses—for that is what is really wanted—with commercial success. For large establishments there is evidence based on practical use that the Upward, the Holmes, and the Lalande batteries are suitable—that is, where cost does not stand in the way. It has not, however, been shown to the satisfaction of the author that any one of them can be used economically for lighting the principal rooms in more modest residences—in a word, for the general public. The author has been met by some with the statement that the general public could at the present time be supplied with electric lighting by primary batteries as cheaply as they are with gas, but that until clients from the wealthier classes, to whom expense is not an object, have been exhausted prices will not and should not be lowered. The author conceives this course to be a mistake, for the process of exhaustion will be slow. Oil lamps and candles are still used in the principal rooms in numbers of mansions, and in the residences of the upper classes, and will continue to be used owing to their effective appearance as works of art—as many of them are—and to the greater purity of the air resulting from the combustion of oil as compared with that of gas.

To popularise the electric light—and to popularise it is the only way to make it pay—it must be cheap and efficient. By cheapness is to be understood either a small first cost and a correspondingly small cost for maintenance, as in the case of a battery placed in the house, or a moderate charge for the supply of the current, as in the case of a central distributing station. The lamps must be adaptable to the present gas fittings, and the cost of the light must be but little in excess of that of the gas of the district. The author does not for one moment ignore the advantages of the electric light from a hygienic or a domestic point of view, he is but too familiar with the unpleasant atmosphere which results from burning gas even with the best burners and in ventilated rooms, although his lucubrations are generally conducted by the aid of an oil

Digitized by Google

lamp. The general public, however, will in the main continue to use the present ordinary methods of illumination, however defective they may know them to be, rather than adopt any new system which entails extra cost, however satisfied they may be that positive advantages are to be gained from it. Men will weigh the extra cost against the extra advantages, and in the majority of cases the former will be allowed to outweigh the latter.

That there are merits in many of the primary systems described—that is, those which have survived their introduction to the public—there can be no doubt, some possessing points which are absent in others. And be it remembered that the list of primary batteries is not exhausted by those described by the author. It might therefore be desirable that a fusion of interests should be effected, and that a committee of independent electricians, chemists, engineers, and sound commercial men, be formed to practically test each battery to destruction. Out of the results might be formulated a system which would meet all the requirements of the general public, and which might eventually be the means of saving the proprietors of those systems which fell short of the mark from absolute loss. The results of this method of applying the doctrine of the survival of the fittest would perhaps press the least inconveniently upon those doomed to suffer by this inexorable law. Of course the author can quite understand every inventor present assuring himself that he is not going to be an absolute loser, but that he is going in to win. The author can only sincerely hope it may be so. Every battery represents a considerable expenditure of time, money, and anxious thought, and every inventor deserves, if he does not achieve, ultimate success.

DISCUSSION.

Mr. W. H. Preece said that his remarks were not intended in the least degree to be critical, and he hoped they were not conceived in an unfair spirit; but he must at once confess that he was to a certain extent an opponent to the introduction of primary batteries for the purpose of distributing light for domestic uses. There were few who had had more experience as to the behaviour of primary batteries than he had, having been acquainted with them for thirty-four years, and he was equally sure that any attempt to utilise them for any such extensive purpose as the lighting of mansions and smaller houses must end in disastrous failure, although there were other uses to which they might be applied with advantage, and, he hoped, with pecuniary success. So many primary batteries had been brought before the public during the last few years that the subject had become nauseating. Most of these, however, possessed peculiar and distinct features. They were almost invariably surrounded with a halo of mystery. There was the depolarising agent, which was a secret—an acid or a solution that was hidden in an atmosphere of Greek or Latin, the result being that all that people knew about them was gained from the high falutin statements put forth in prospectuses and interested descriptions. But amongst the numerous failures there had been one or two successes. One very promising battery that at some time would certainly make a stir was that which Mr. Nursey had described as the Holmes and Burke battery; another which was a distinct departure was the Upward battery, and why that one had not been more practically developed he had a great difficulty in understanding. It seemed to meet the want for something which would come between that point where a gas engine or a secondary battery might be introduced and the point where a small battery could be used for mining or other similar purposes. It had not yet received that development it deserved. Mr. Nursey's paper dealt largely with the theoretical side of the primary battery question, but was there any gentleman in the room who could tell them the practical result of twelve months', or of six, or even three months' continuous work? That was what practical men wanted more than anything else to know. The field in which primary batteries were going to make a stir in the world was not that of house lighting; it was in supply of safety lamps to those who endangered their lives for our comfort. There was no greater want in this age than that of some handy portable, convenient light that men could carry about with ease and safety in mines. He mentioned as a fact within his own knowledge that some time ago 2,600 electric safety lamps had been ordered for collieries in the neighbourhood of Cardiff.

Mr. March, accepting Mr. Preece's challenge, described the practical working of the Holmes-Burke battery for a period of more than a few months. He said that two years ago he had installed 40 lamps of 10 candles supplied by a Holmes-Burke battery, and that installation had worked with perfect satisfaction to its owners ever since. The cost, of course, was more than gas. He thought they would be too sanguine as yet to expect electric lighting to be as cheap as gas. He put down the cost of the Holmes-Burke battery as being something like double the price of gas at 3s. or 3s. 6d.

After a few words from Mr. Clifton, who proceeded to give a description of the Eclipse battery,

Mr. Ross said that his battery was a zinc and carbon one, and the only mystery there would be in regard to the solution was that he had occasionally called his oxidising liquid "Eureka;" but he was quite prepared to explain what the liquid was. It was a very economical one, being composed of three parts of muriatic acid, three parts of water, and one part of another strong oxidising agent. He generally used a peculiar kind of fuming nitric acid—that was to say, what was usually called nitrous.

Mr. Fergusson said he was interested in the Lalande battery, with which in the year 1886 quite 1,000 lights were run. The only point in regard to the Lalande battery as to which there had been any doubt was in reference to the getting back of the zinc. There was no doubt that that could be effected. They were getting it back now in the form of metallic zinc of a very pure quality, and he hoped shortly to be able to send a sample to Mr. Preece especially for Post Office purposes to prevent local action, and he thought that when Mr. Preece had tested that sample it would convince him that though it was possible to use primary batteries for domestic lighting that the residual products were also of value.

Mr. Upward said that his battery had been employed at the Manchester Exhibition, University College, Liverpool, and at Messrs. Woodhouse and Rawson's offices in Queen Victoria-street as well as by the Government of Valparaiso. Since it had been first introduced it had been very much simplified. The great object had been to get over the large number of chlorine connections.

The Earl of Galloway gave some interesting particulars in connection with secondary batteries furnished from the working of the Elieson locomotives on the tramways at Stratford.

Mr. Binswanger endorsed the remarks of Mr. Preece, and stated that the Pollak battery, in the introduction of which he was concerned, he had found to fail for the purpose for which it was intended. He was now interested in the Friedlander battery, the pretensions of which were very modest, and which was intended only for table and medical uses.

Mr. Pearson said that he was present to represent Lord Onslow as an intending purchaser if any one would put before him a battery which would replace that which had been in Lord Onslow's house for some time, but which had proved a failure. He was afraid that he should have to go away from the meeting with the impression that he had when he came to it, that primary batteries were not adapted for general house lighting.

Mr. FitzGerald said that in common with other electricians he had been astounded at the statements which had been put forward on behalf of a number of primary batteries which had been disinterred from the limbo of past failures, and which had been experimented upon twenty-five or thirty years ago, and which were at that time condemned. He must, however, except from these strictures the chlorine battery of Mr. Upward, and also the Lalande-Chaperon battery, which had some extraordinary properties, and which in a higher degree, perhaps, than any other battery possessed the capacity of supplying large currents—being condemned only by its E.M.F.

Mr. Rawson said that the reason why the Upward battery had not been more heard of during the last year was that he preferred to make it as perfect as possible before putting it in the market. In its present state it was the result of a great many years' work on the part of Mr. Upward, and he believed they might look forward to twelve or eighteen months' harder work before they would get it into a form when they might say it was fit to take the place of a dynamo or gas engine for lighting houses with 50 or 100 lights.

After some remarks from Dr. Fleming, the proceedings terminated.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

STUDENTS' MEETING.

A meeting of the students of the Society of Telegraph-Engineers and Electricians was held on Thursday, the 17th inst., Prof. Perry, M.E., D.Sc., F.R.S., in the chair.

Mr. J. Rance, jun., opened a discussion upon Profs. Ayrton and Perry's paper, "Modes of Measuring the Coefficients of Self and Mutual Induction," explaining various forms and uses of the secohmmeter, including the latest form, the reversing secohmmeter, the advantages claimed for this form of instrument being (1) The sensibility is doubled; (2) may be used when the magnetic circuit is closed; (3) the battery circuit is broken for a very short time; the E.M.F., therefore, does not change much.

Reference was also made to Mr. Sumpner's paper, "The Measurement of Self-Induction, Mutual Induction, and Capacity." Owing to the kindness of Profs. Ayrton and Perry many instruments and diagrams were exhibited. The discussion was maintained by Messrs. E. W. Smith, Cooper, Bate, Dykes, Lamb, and Prof. Perry.

After thanking the Chairman for presiding, the meeting terminated.

The next Students' Meeting will be held on Thursday, December 1.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

Note.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

15,600. W. Price and J. Gerrard. Preston. An improved electric circular switch railway. November 15.

15,640. W. H. Scott and A. E. Paris. London. An improved method for regulating the electromotive force of secondary circuits. November 15.

15,653. H. H. Lake. London. Improvements relating to electrical apparatus for signalling in railway trains and to coupling devices for use therewith (The D. M. Electrical Train Signal Co., Incorporated, United States). Complete specification. November 15.

Digitized by Google

15,660. A. J. THOMAS. London. Improvements in electric clocks. November 15.

15,703. J. COURT. London. A galvanic battery for medical purposes. November 16.

15,717. C. A. RANDALL. Brompton. Electrical date and time stamp. November 16.

15,721. A. W. ARMSTRONG. London. An electrical movement or mechanism for the automatic sale of goods. November 16.

15,726. N. K. CHERRILL. London. Improvements in conductors for use in incandescent electric lamps. November 16.

15,730. J. VAUGHAN-SHERRIN. Kent. Improvements in galvanic batteries (complete specification). November 16.

15,736. W. R. LAKE. Improvements in electrical indicating or signalling apparatus (C. Grivolas, France). November 16.

15,754. W. J. S. BARBER-STARKEY. Manchester. Improvements in the electrolytes of secondary voltaic batteries. November 17.

15,760. W. WEBSTER. London. Improvements in the electrolytic treatment of sewage and sea-water for the production of certain products therefrom and apparatus therefor. November 17.

15,779. A. J. JARMAN. London. Improvements in the construction of electrical motors. November 17.

15,801. W. H. BECK. London. Improvements in incandescent lamps (A. M. Michel, France). November 17.

15,858. W. MAIN. London. Improvements in dynamo-electric machines and electro-motors (complete specification). November 18.

15,883. W. G. ADAMS. London. Electric safety lamp apparatus. November 18.

15,887. A. W. ARMSTRONG. London. An improved electrical automatic delivery box. November 19.

15,891. W. H. DOUGLAS. Birmingham. Improvements in instruments for measuring electrical currents. November 19.

15,922. A. COLEMAN, H. F. JACKSON and E. L. DUDLEY. London. An improved spring jack for telephonic and other electrical purposes in which it is desired to change or switch a current from one conductor to another. November 19.

15,939. W. WEBSTER. London. Improved apparatus for the electrolytic treatment and other impure liquids. November 19.

15,943. O. C. D. ROSS. London. Improvements in galvanic batteries. November 19.

15,965. A. S. DUNN. Glasgow. A new or improved apparatus for use in erecting or renewing telegraph, telephone and other wires. November 21.

15,985. E. BERGHOLT. London. Automatically diverting and restoring the course of an electrical current. November 21.

COMPLETE SPECIFICATIONS ACCEPTED.

NOTE.—*All persons interested in opposing the grant of a patent on any one of the undermentioned applications may, at any time within two months from the dates in italics, give notice at the Patent Office in the prescribed form of such opposition.*

November 19th, 1887.

15,722. J. Y. JOHNSON. London. Improvements in electric telegraphs (A. M. Rosebrugh, Canada). December 1, 1886.

November 23rd, 1887.

1,738. C. D. ABEL. London. Improvements in dynamo-electric machines (the firm of Siemens and Halske, Germany). February 3.

PATENTS SEALED.

November 15, 1887.

13,641. B. J. B. MILLS. London. Improvements in the means for indicating and for regulating the electrical potential in systems of electrical distribution (J. W. Howell, United States). October 25, 1886.

14,568. A. HOWAT. Manchester. Improvements in electric safety lamps. November 11, 1886.

10,866. C. ACCIOLI DE AZEVEDO BASTO. Brazil. An improved motor. August 8, 1887.

November 18, 1887.

11,720. C. P. SHARPLEY. Staffordshire. Improvements in couplings, chiefly applicable to railways, vehicles and their fittings, such as brake pipes or rods, electric conducting wires and the like. September 15, 1886.

14,106. C. POLLAK and G. BINSWANGER. London. A method and and apparatus for conducting electricity to moving vehicles. November 2.

14,489. C. SMITH, London. Improvements in apparatus for lighting railways, carriages, and tramcars by electricity. November 9, 1886.

14,563. J. S. SELLON, Kent. Improvements in secondary batteries. November 10, 1886.

10,933. D. S. ROBERTSHAW and R. F. SUNDERLAND, Yorkshire. Improvements in means or material employed for insulating electric currents. August 10, 1887.

SPECIFICATIONS PUBLISHED DURING THE MONTH.

13,971, 1886.—H. R. FISHER. Electric portable battery and lamp. (Price 8d.)

12,222, 1886.—R. J. RUDD. Electric apparatus for indicating time. (Price 8d.)

16,440, 1886.—W. J. MACKENZIE. Electric arc lamps. (Price 8d.)

16,662, 1886.—R. P. SELLON. Automatically regulating electric generators.

16,908, 1886.—W. ARMSTRONG. Effecting electrical signals between the occupants of cages, hoists, &c. (Price 8d.)

893, 1887.—G. W. HOOK. Electrical billiard marking repeater and indicators. (Price 6d.)

COMPANIES' MEETINGS.

South of England Telephone Company (Limited).

A half-yearly general meeting of this Company was held at Winchester House, No. 50, Old Broad-street, yesterday, under the presidency of Mr. D. Owen Bateson.

The SECRETARY (Mr. Fred. L. Robinson) having read the notice convening the meeting,

The CHAIRMAN said: In compliance with the resolution passed at our general meeting in June last we have called you together to-day. I think, however, that we could have told you everything relative to the Company's progress by circular instead of giving you the trouble to attend personally; but as far as your Directors are concerned, they have not the slightest objection to the meeting, and it affords them the opportunity of rendering an account of their stewardship during the past half year, and of answering any questions upon which the shareholders desire information. The time under review has been extremely uneventful; indeed, I may say we are in the happy condition of that country that has no history. We have met with no disaster of any kind, as far as I am aware, and our progress in new work has been to a satisfactory extent. Our system has withstood the gales of the autumn, proving that the lesson taught by the collapse last winter has been well learnt. The number of our exchange lines has increased by 186 and private lines by 25, and our gross rentals show £1,500 increase for the half year. We have laid trunk lines between the towns of Brighton and Lewes, Brighton and Shoreham, and between Margate, *via* Broadstairs, and Ramsgate. This latter line is intended to be connected with Westgate as soon as we can get wayleaves through. The Brighton and Lewes line is an instalment towards Eastbourne. At the moment the latter route is suspended—temporarily we hope—consequent on wayleave difficulties, which we trust may be got over ere long. The Margate and Ramsgate exchanges are in process of development, and we think they give good prospect of success eventually, though this year we have great complaints of the unprofitableness of the last season in both places. Our centres north and west of London are doing a good steady business. Reading makes satisfactory progress, and Cambridge is doing very well. I am sorry to say that Oxford lags sadly behind the sister University, and we find much difficulty in getting along there. Northampton, Norwich, and Ipswich are doing pretty fairly, though perhaps hardly as well as we could wish. We have great complaints of the badness of trade in these districts. Our other stations are well seen to, and whenever we see a prospect of doing any paying work our energies are devoted to looking after it. I am glad to say that as a rule the public bodies in the various towns we are in welcome us in the light of public benefactors, and give us valuable assistance. Here and there, however, individuals give us some trouble and impede our progress; but, upon the whole, we have really little to complain of on this score. Our relations with the Post Office are of the most amicable kind. We never have any controversy with this branch of the public service. I must also bear my testimony to the kindness and consideration of the various railway companies in our district, both in granting us wayleaves, &c., and in renting lines from us where they can be made useful. We always endeavoured to put them on the most favourable terms possible as regards cost. I regret to say we have come no nearer to a junction of our system with that of the United Company in order to enable our subscribers to converse with London, and *vice versâ.* We have loud and continuous complaints that we are unable to effect this most desirable end, and have made representations to the parent company about it. As you are aware, we do not produce any financial statement at this period of the year. I may, however, state that your Directors are satisfied with the progress of the business, and they have every expectation that at the annual meeting in the spring of next year they will be able to give a good account of themselves. I have no resolution to propose on this occasion.

Mr. WM. ROE (Ipswich) observed that at the last meeting he had to take up a position somewhat in opposition to the Directors' views; but he was not in that position that day. He had endeavoured, in conjunction

Digitized by Google

with a friend, to get a trunk line established from Ipswich to Stowmarket, and he felt convinced that if they could succeed in that they would be able to get a trunk line from that point to Felixstowe. They, however, found their efforts rendered difficult in consequence of the terms asked by the Company. Some merchants hesitated because they were required to pay £10 for the Exchange, as well as £6 for the trunk line. That was £16 a year. He was very anxious to get the trunk line to Stowmarket, and he asked whether some modification could not be made in the terms referred to. If that could be done he felt that they could obtain the necessary permission for the line to Stowmarket.

The CHAIRMAN said they would be glad after the meeting to talk the matter over with Mr. Roe. The Directors had been trying to obtain the line in question for the last two years, and they were anxious to run it as soon as ever they could see a paying price. They could not run speculative lines, and his experience was that if once they ran a line without getting the orders before, they never got them after.

Dr. ELLIS (Eastbourne) said he thought the account of the six months' working should satisfy any shareholder in the Company. If such rate of progress went on, there was no doubt whatever that the success of the Company as a dividend-paying one was assured, and that they could look forward to an era of steadily increasing prosperity. He thought it was advantageous that they should meet once every six months. There were one or two points to which he would like to draw attention. He thought it would be very advantageous if there could be an extension of the lines to the post offices throughout the district, so that telegrams might be sent direct from the houses in the suburbs. In many cases where the houses were at a considerable distance from the telegraph offices, particularly in the winter, that would be a great boon. The Chairman had referred to the terms on which they stood with the railway companies. He thought that every railway station should have a telephone—at all events, that all first-class stations should have telephony in their offices. He gave an instance which had come under his notice of the importance of this—a doctor having been communicated with by means of the telephone, and brought within a few minutes to the assistance of a gentleman who had fallen down in a fit at the station. He had heard that in a neighbouring town to Eastbourne the Company had experienced great opposition to the introduction of the telephone unless certain special facilities were given to certain people, and that there had been some threats about cutting the wires. He was sorry that a suggestion which he made at the last meeting had not been acted on—that the Directors should do something to give information to the general public as to the working of the telephone. There seemed to be a great deal of ignorance on the subject, and when he had invited some of his acquaintance to speak through his telephone they had declined, and in a manner as if there was something uncanny about the instrument. Again, in the case of Hastings people said that they wanted underground wires; but such a wish could only have been inspired through ignorance, for the cost of underground wires would be so great that an exchange at Hastings could not pay.

The CHAIRMAN, in replying, stated that with reference to telephones at railway stations, the Post Office objected, and they had a voice in the matter. They had been trying very hard to get a telephone placed at Brighton station, but they could not succeed. He had been down to Brighton two or three times to see whether they could not get one as near as possible to the station. The authorities of Hastings had thrown a certain amount of difficulty in their way; but the opposition there had been more particularly from private individuals, who had had perfect information with respect to the difficulty and to the expense of going underground. Only last week he was at Hastings on the subject. He was almost afraid that some day they might have their wires cut, but he could not agree that it was desirable that they should let their wires be cut if they could induce a more favourable feeling. It was to be remembered that there was the cost of replacing the wires, and that as soon as the man's wire was cut he considered that his rental ceased.

Dr. ELLIS said that what he had meant to convey was that he would rather allow a man to cut the lines crossing his property than give way to him—than, for instance, let him have a wire free.

The CHAIRMAN said he fancied that such a matter as that must be left to the discretion of the Directors. Sometimes a line was absolutely necessary for them. They had the greatest difficulty as to crossing Warrior-square, Hastings, and he did not know whether they would have to go underground. They had 16 or 17 wires going over Warrior-square, and they had notice at present to remove them. If they saw their way to giving information to the public in regard to the telephone, as Dr. Ellis had suggested, they would be very glad to do so.

Mr. ROE said he thought a great increase of business would follow if they could put private residences in the suburbs on the telephone at a smaller cost than commercial people. Such persons would communicate with those tradespeople who had the telephone, and other tradespeople, seeing that, would then desire to have the same means of communicating with customers.

The CHAIRMAN said they tried to get as many suburban people on the Exchange as they could, but the further a man was away from the Exchange, the more expensive it was to put up a line for him. As a rule they could not very much reduce their rates, which were now lower than those of any other company in the country. They had been trying latterly to establish call offices with call boxes in the outskirts of towns, and in towns also, where any one could use the telephone on payment of a small fee—threepence or sixpence, according to distance.

Mr. KLENCK expressed his belief that the difficulty at Hastings would be very much alleviated if a deputation from the Board went there. He was connected with a certain company, and a difficulty arose with the authorities at Bristol. A visit from the Directors resulted the removal of the difficulty.

The CHAIRMAN stated that only last week he was at Hastings, but the objection to going over Warrior-square was not on the part of the Corporation.

A SHAREHOLDER: You must go round it.

The CHAIRMAN replied that for the last two years they had been trying to get wayleaves round it. They could get on at the west side of Warrior-square, but they could not get an attachment on the east side, where one proprietor objected.

Mr. STEWART said he had no doubt that the Directors would succeed, through friendly negotiations, in removing the difficulty which had arisen.

The meeting then terminated in the usual manner.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 18th inst. amounted to £4,443.

GERMAN UNION TELEGRAPH AND TRUST COMPANY.—The directors of this company report to the shareholders that the German Government have offered to purchase the cables and property of the German Union Telegraph Company of Berlin at a price which the directors reckon, after payment of expenses of liquidation in Berlin, will leave about £9. 10s. or £9. 15s. per share for the shareholders of the German Union Telegraph and Trust Company (Limited), payable in January, 1889. The dividends in respect of profits for the year 1887 will be paid at the usual time—viz., interim in January, 1888, and final in March, 1888. It is estimated that these dividends will yield from 7 to 7½ per cent. on the shares of this company. The directors recommend the acceptance of the offer of the German Government.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 18th were £3,595 (after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company).

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 15th November are £2,609, as compared with £2,129 in the corresponding period of 1886. The July receipts, estimated at £4,762, realised £4,851.

NOTICE OF REMOVAL.—Messrs. Duncan Brothers, engineers, of 32, Queen Victoria-street, E.C., intimate that on and after the first day of December their business address will be 2, Victoria-mansions, Westminster, S.W.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 498.—Vol. XX. FRIDAY, DECEMBER 2, 1887. Price 4d.

NOTES.

The question, What is an Electrician? was asked at the Electric Club last month, by Dr. Leonard Waldo, of Yale College, U.S., but was not precisely answered either by himself or the gentlemen who discussed his paper, the prevailing notion being that, like the question, What is a Philosopher? very much depends upon what you mean by it. The nearest approach to a definition, we are gratified to notice, was given by our countryman Professor Forbes, who happened to be present, and who told his audience that an electrician pure and simple is a physicist, but that the electrician of whom they were talking is an electrical engineer or an electrical inventor—two classes of persons by no means necessarily the same. Mr. Swinburne, also one of the guests, seems to think otherwise, for he asserted, with more fluency than accuracy, that we turned out in this country accomplished electricians at the rate of about a dozen a week, and would be glad to export them to supply the American market. Well, if they have no objection, we have none to offer, provided the Americans will send over to us the surplus electrical work which at present they cannot find electricians enough to perform. We rather think we should not be the losers by this reciprocity.

Although disparaging things are sometimes said of our American kinsmen's science, there is no gainsaying their practical good sense, a sample of which will be found in the *School of Mines Quarterly* (New York) for last month. Its article entitled "What are the Requirements for a Course in Electrical Engineering at a Technical School?" ought to be read by every Englishman interested in this subject, and especially by those (if any such there be) who are inclined to dissent from the views put forward in our own leader last week. Starting from the proposition that "the commercial field of the physicist-electrician *by itself* is very limited," the writer, after careful discussion of the whole subject, arrives at a conclusion almost identical with our own, namely, that the rising students of electrical engineering "should be trained first as mechanical engineers, and upon that foundation the special electrical structure should be erected." Finally, he asks the question, whether in these days of electrical industry it would not be well to "make the course and degree of the mechanical engineer in the university cover as much of electrical knowledge in addition to its other requirements as would render its graduates competent for the electrical positions which they are likely to be called to fill?" It is needless for us to remark that in this country, as in America hitherto, the process above suggested has been exactly reversed, and with by no means encouraging results.

On a kindred subject, that of general technical education, we must confess that America is ahead of us, if not in practice, at all events in arguments. The *New York Times* supplies us with one which throughout our long discussions on technical education we seem to have entirely overlooked. It is an argument against all attempts at teaching handicrafts, by the aid of taxation, which do not include the manifestly impossible task of teaching every handicraft. Why, it is asked, should a man who desires his son to be a shoemaker be compelled to bear the expense, and at the same time pay taxes for having his neighbour's son taught, say, carpentry? Why, indeed? And if carpentry and masonry, why not law and divinity?

The audience at the meeting of the Society of Telegraph Engineers was without doubt greatly interested in Profs. Ayrton and Perry's very beautiful and ingenious modification of the Cardew voltmeter. We thus describe it because we feel that we, in common with all electricians, owe a debt of gratitude to Capt. Cardew for giving us the principle of heat-expansion for voltmeters, and not because we are forgetful of the fact that in this new instrument great originality and true invention are conspicuous. For the measurement of alternating potential differences we have hitherto been dependent almost entirely on the Cardew instrument, for the electrometer is a laboratory rather than a workshop and engine room instrument, and is, further, except in its more delicate forms, only suitable for the measurement of very high potentials. But the Cardew voltmeter is almost useless for anything under 20 volts, and does not always prove a sure guide in the parts of its scale where it is expected to be correct. Our experience of this instrument may have been rather unfortunate, but we must confess that the quality which has most recommended it to us has been its great convenience, rather than its accuracy or freedom from change. And in this respect we fear that the instrument to which Prof. Ayrton introduced us the other evening can scarcely be expected to effect a radical cure, as, being founded on the Cardew principle, it must to some extent share the disadvantages as well as the advantages of its prototype. Nevertheless, it is a very interesting contribution to the series of practical measuring instruments for which we are indebted to the ingenuity and skill of

Digitized by Google

Profs. Ayrton and Perry. We have had enough, and more than enough, of instruments which merely enable us to do in another way—and not better—what can already be done by several old and tried appliances. We want improvements, not simple varieties; and, above all, we want reliable and simple instruments for alternating current work.

SOME twelve months ago one of the most ingenious experimenters with whom we have the honour to be acquainted constructed a voltmeter based upon the Cardew principle, and not wholly unlike that of Profs. Ayrton and Perry. This instrument, although minus the advantage of an Ayrton and Perry spring, yet possesses one feature of very great value which is not found in the other types. We are not at liberty for the present to give a detailed description of the instrument, although we hope to be able to do so before long.

CAPT. CARDEW's story of the voltmeter with an 18in. dial is really very funny. This instrument was required for an engine room at Chatham, and was ordered to be of such a size as to be readable at a distance of at least forty feet. But no sooner was the apparatus made than it was discovered that, in the only position where room could be found for it, it was impossible to get more than two feet back from the dial.

BUT this is, probably, not by any means the largest Cardew voltmeter which has been made. Two or three of the London manufacturers possess, or have possessed, such apparatus of Brobdingnagian proportions, but the largest of which we have any knowledge was erected by Mr. Nelson Cherrill, in the Swan lamp factory at Lille. The wires were in this case carried up through several floors of the building. They were, if we recollect rightly, of iron, and quite satisfactory results were obtained.

ALTHOUGH comparatively little of a novel character has of late been heard from the owners of the chief patents connected with storage batteries, we happen to know that they are not suffering for want of attention. Amongst other things, considerable attention has been devoted during the last twelve months to the production of a type of cell especially suited for electric traction. There can be little doubt (*pace* the Bentley-Knight Railway Company) that a very extensive field is being rapidly opened up in this direction. And there can be still less doubt that the requirements of a storage battery to meet this work are of an extremely exigent nature; and further that they have been fully satisfied by no single cell at present in the market. Every impartial observer who is acquainted with the facts of the case will bear us out in this assertion. It is therefore highly satisfactory to learn that the E.P.S. Co. have been quietly devoting considerable time, money and skill to the solution of this pressing problem.

SECONDARY batteries are likely before long to claim attention on other grounds. An important scheme is afoot for supplying some four or five thousand lamps in a certain London district by means of local batteries charged in series from a central station. We might more briefly have characterised the system by the mystic letters B. T. K.; but, although the general principles are the same as those which were (not) carried out at Colchester, it would be invidious and unfair to brand the new experiment with the failure of 1883. Much has been learnt since that date, and we are confident that the new attempt will at least start under fairer auspices, and with every chance of success which matured experience, acquired skill, and improved appliances can give it. We shall hail a successful result with unqualified satisfaction.

THE pamphlet issued by the E.P.S. Co., in which the advent of the venture above referred to is foreshadowed, opens, naturally enough, with a vigorous attack upon all systems of distribution—especially transformer systems—in which entire dependence is placed on moving machinery. There is very little in these elaborate strictures with which, *from an a priori point of view*, we should be inclined to differ. The engineer who undertakes to light a district without any species of reservoir on which to depend in the event of accident to his machines undeniably undertakes a very serious responsibility; but, on the other hand, we confess that it appears to us that the question as to whether or not the engineer is *justified* in undertaking this responsibility is one which can only be settled by an appeal to practical experience. Arguments of a precisely similar character would *a priori* tell with equal force against a railway system; but our railways, which altogether depend upon the continuously reliable performance of manifold and intricate mechanism, do, as a rule, discharge satisfactorily the services expected from them. So with central station lighting, minus storage batteries; the last few years have seen a gradual accumulation of evidence that properly designed engines and dynamos in competent hands can be entrusted to perform their functions with a degree of certainty which may be considered within the limits of the practical requirements of the case. And after all this is not saying very much.

BUT, other things being equal, let us by all means have a storage system. One *other thing* here chiefly to be considered is the price which must be paid for the additional safeguard. In the scheme just alluded to the tariff has been fixed at 8d. per unit. This is by no means a high figure, and we are informed that every precaution has been taken not to underestimate the cost.

So far as London is concerned fogs seem to us to be the great enemies of this system. The scheme provides at present for the installation of two sets of cells at each station, each capable (we presume) at a push of undertaking the whole of the local circuit. The two batteries are each to be charged for a period of eight hours per diem, but the engine power estimated for is only 2 3rds that required for the direct supply of the whole of the lamps. What, then, happens after two days' heavy fog?

OUR esteemed correspondent, Mr. O. C. D. Ross, really does us too much honour. We cannot but feel gratified that in accepting Mr. William Webster jun.'s challenge he expresses a

Digitized by Google

desire that the arbitrament should be placed in our hands. We hasten to state that while sincerely anxious to be of service in the matter we had not contemplated, and do not see our way at present to accept, the position of umpire. But this point need offer no difficulty; at least, we think not. As to Mr. Ross's amendments to the terms of the contest, they are so reasonable that we have little doubt that an agreement will be arrived at *nem. con.* We most cordially endorse the suggestion that the emission of noxious fumes should constitute an immediate disqualification. A letter from Mr. Shippey on the same subject has reached us since writing the above.

THE P.B. epidemic has broken out in a severe form in the United States; witness the following extract from a P.B. advertisement (circ. November, 1887) in the *New York Insurance Journal*:—"In this system the electricity is generated and supplied by the batteries composed of essential and ultimate elements which, being in ordinary sized jars, are easily handled and readily portable." . . . "With the exception of this trivial waste (the element being merely nominal in cost), and the constant renewal of the preparation, there is no other expense attached to the maintenance of the plant, as the ultimate elements retain their initial efficiency for many months—possibly years." From this it is at least clear that unessential and approximate elements are not in it, as compared with the "essential and ultimate" variety.

AN energetic provincial contemporary, the *East Anglian Daily Times*, whose offices, as we happen to know, are lit throughout with electric light, has recently devoted considerable space to enforcing the advantages and practicability of central station lighting. Our contemporary's enthusiasm has been not unnaturally aroused by the fact that, with the assistance of Messrs. Paris and Scott, its own electrical plant has been utilised for lighting the Public Hall at Ipswich on the occasion of a *conversazione* of the Ipswich Scientific Society. After remarking that "in this carriage of light along the streets there is no loss of power," our contemporary proceeds to show how, by means of motor-generators, distances far exceeding a quarter of a mile may be covered. The following passage, if not exactly scientific, is extremely eloquent:—"To light houses at Rushmere, for instance, the electricians would carry from the central engine station a small copper cable about the thickness of telegraph wire. The smaller wire gives higher energy, the electricity dashing along it like a stream confined in a rocky channel. On the thick, roomy wire the electric current has space to flow along like a broad and placid river; on the narrow wire it becomes confined and impetuous, and on reaching its destination would smash the delicate lamps, and act generally after the manner of torrents. So the electricians use the vigorous power thus produced as a motive force, turning with it a dynamo, which generates fresh electricity of its own. The thick, shorter wire carries, as it were, direct light, though you cannot see it as it goes along the street. The small long-distance wire conveys power and energy from which light is made. So the electricians are now ready to light workshops and houses at great distances from the central station, and the time seems at hand when by union and organisation men should begin to utilise the power they possess to a far greater extent than has hitherto been done."

THE Brussels Exhibition of 1888, even at this early stage, gives promise of a highly successful issue. The selection of Mr. Lee Bapty as the representative of the British section will go a long way to ensuring the confidence of exhibitors from this side the Channel; while in the electrical and electric lighting sections no better selection could have been made than M. Mourlon as chief superintendent, with M. Bandsept as chief engineer. Both these gentlemen are well known and as highly esteemed in electrical circles in this country, as well as in their own.

Indian Military Telegraphs.—The military telegraph line through the Khyber Pass has now been completed between Jamrood and Lundi Kotal. This brings the wire within 140 miles of Cabul.

Telegraph Appliances.—We have received from Messrs. Spagnoletti and Crookes their illustrated catalogue of apparatus, tools, and materials required for the construction and working of railway telegraph lines.

The Brussels Exhibition.—In the electrical section of this exhibition proposals are invited for laying down a tramway line, the cars to be drawn by electric motors, supplied from accumulators. Both automotor cars and separate engines are to be employed.

Brighton.—At a meeting of the Brighton Town Council, held on November 24th, in moving the adoption of the report for the electric lighting at the Pavilion, Mr. Alderman Abbey stated that a considerable saving, amounting to £340 a year, had been effected by the use of electricity.

Award.—We are pleased to learn that the Woodhouse and Rawson Electric Supply Company (Limited), of Great Britain, acting as agents to the Electric Gas Lighting Company, have received the highest award, namely, a Diploma of Honour, for their exhibition of electric lighting appliances, burglar alarms, &c., at the American Exhibition recently closed.

Ramsgate.—Messrs. Sherrin, Vaughan, Sherrin and Co., who have recently commenced business as electrical engineers at Ramsgate, have completed an installation of some seventy lights at the offices of Messrs. E. G. Westall and Co. Messrs. Sherrin inform us that from orders and inquiries on hand they anticipate a prosperous future for the electric light in the Isle of Thanet.

Manchester: Lecture on Central Station Lighting.—On Saturday last Mr. J. R. Williamson read a paper before the Manchester Association of Engineers, at the Grand Hotel, Aytoun-street, on "Electric Lighting from Central Stations." Mr. Williamson treated the subject with marked ability, and devoted his remarks chiefly to the modern methods of distribution by transformers.

The Royal Yachts.—A Portsmouth telegram states that a proposal to supply the two principal Royal yachts with the electric light has been submitted to Her Majesty, who has given her consent on condition that the new light is not introduced into the state apartments of the "Victoria and Albert." There is no objection to all parts of the "Osborne" being electrically lighted. The estimate as to the cost is to be

Digitized by Google

sent to the Admiralty, and it is understood the work will be carried out while the usual winter repairs are in hand.

Manchester.—The Manchester correspondent of the *Engineer* states that Messrs. Richard Hornsby and Sons, of Grantham, have obtained the contract for the whole of the engine and boiler power for the electric lighting, heating, and ventilating of the enormous building which is being erected in Manchester for the purposes of Buffalo Bill's Wild West Show. Besides a large number of smaller lamps, there will be twenty-five large arc lamps; and there will be about 8,000ft. of steam piping for heating. The Brush Company is supplying the electrical plant.

Rheims.—The municipality of Rheims has had before it a proposal from the Société Lelarge-Edison for the electric lighting of a limited central area of that city. The council, considering the smallness of the proposed area and the absence of obligation on the part of the company, has resolved to decline the proposal, while at the same time it holds itself ready to consider the question favourably when an electric company offers to light the whole of the town on terms resembling those under which the Gas Company is at present carrying on its business.

"Wickwar."—The *Trowbridge Chronicle* says:—"The electric light is to be introduced into Wickwar; streets, roads, and public buildings are to be lighted therewith. Mr. H. Wiles will provide all motive power, erection of lamps, &c., at an infinitesimal cost to the inhabitants. Then a committee, who is a guarantee for seven years, will find the funds required for streets and railway station road." We congratulate the village, town, or city of Wickwar (? Is this a printer's error for War-wick) on possessing such enlightened and philanthropic residents as Mr. Wiles and his committee.

The Indian Telegraph Department.—It is said that a despatch from the Secretary of State regarding the block in promotion in the Telegraph Department authorises the Government of India, with a view to facilitating promotion, to offer exceptional pensions to a large number of officers, as an inducement to retire before the time when, under existing rules, they become entitled to pension. The officers chiefly affected by this offer are those who came out in the years 1869, 1870, and 1871. A reorganisation of existing grades in the Department is also believed to have been ordered, and it is hoped that it will afford immediate promotion to several officers.

Dublin.—The Corporation of Dublin will, on or before Friday, the 9th inst., receive tenders for the lighting with electric light of streets in the city of Dublin, in length about 1,950 yards, for a period of seven years, from 1st July, 1888. The parties tendering shall be bound to supply, erect, fix, and maintain all the necessary plant, machinery, engines, boilers, dynamos, conductors, pillars, &c., at their own expense. Water power is available on the property of the Corporation at Island Bridge, about two miles from the streets to be lighted. Specification, form of tender, and ground plan of Island Bridge and streets proposed to be lighted, can be had at the office of Mr. Spencer Harty, C.E., borough surveyor, City Hall, Dublin.

Submarine Arc Lamp.—Messrs. Cox, Robinson and Co., of Liverpool, have brought out a submarine arc lamp specially for divers' use in wells. The body is of Delta metal, hexagon shape, with gland at the top for the cable. The globe is a cylinder of annealed glass, ¾in. thick, 14in. long, and 10in. diameter. This is ground perfectly flat at each end, and then cushioned on thick india rubber pads held between two circular plates by means of vertical metal rods, which also act as guards. The whole is then fastened to the body by means of wing nuts and hermetically sealed by placing india rubber discs between and applying any desired amount of pressure by means of the nuts. This lamp will stand a pressure of 140lb. to the inch.

The "Watt" System.—The *City Press* states that "the "Maxim-Weston Company has already received a large "number of orders for the new 'Watt' system of lighting, "and are in communication with the authorities of the city "and other large centres for the purpose of street lighting. "The company claim that they are now in a position to "obtain six arc lamps of 150 candle-power, in place of one "as heretofore, from one electrical horse-power, and that "they are thus a long way in the van as compared with "their competitors. Mr. Watt, whose untiring energies in "the electric field deserve success, will probably shortly "be in a position to enlighten the darkness of this, the "'Metropolis of the World,' by means of his recent dis-"coveries."

Exeter.—An informal and private meeting, convened by circular, was held recently at the Victoria Hall, Exeter, to discuss the propriety of forming a company for the purpose of supplying the City of Exeter with the electric light. The proceedings were held in the interest of the promoters of the Thomson-Houston system, and there was a fairly numerous attendance, among those present being the Right Worshipful the Mayor. No definite steps were taken, but several gentlemen present offered to take shares should a company be formed. In the meantime Mr. Massingham proposes, with the consent of the authorities in the erection of the wires, to light experimentally a central area of Exeter, the Albert Museum, the Athenæum, and the establishments of several tradesmen. A second meeting to further consider the proposal of forming a company is to be held shortly.

India.—The viceregal palace at Simla is to be supplied with a very extensive installation of electric lights. We understand that the matter has been placed in the hands of Mr. W. H. Massey, of Twyford, Berks.—Our contemporary, *Indian Engineering*, has the following paragraphs:—The electric light has been introduced into the East Indian Railway collieries at Giridhi, and marks the opening of a new era in Indian mining. The miners are said to be delighted with the innovation, and go to their work with greater confidence than before.—The subject of electric tramways is likely to come under the notice of the authorities in India before long. We understand that arrangements have been made in London to supply the city of Madras with a tramway system on the new principle, pending the acceptance of the offer by the authorities on the spot.

Projector Signalling on Clouds.—In our issue of Nov. 18th we described some experiments recently carried out at Newcastle-on-Tyne on the possibility of transmitting signals by projecting a powerful beam of light on the clouds and flashing Morse signals. About the same time a similar experiment was made at Singapore by the officers of two ships of the Royal Navy on the East Indian station. The "Orion" was in port at Singapore, and the "Espoir" left for Hong Kong at a given speed of 10 knots per hour. When she had been gone long enough to have covered 60 knots the "Orion" flashed a message to her by means of the electric light directed against the clouds. It was not known at the time whether the message of four words was understood or not, but the "Espoir" has since reported that it was made out and replied to. It thus appears that the experiment was only partially satisfactory, but even this shows the possibility of flashing signals to distances hitherto undreamed of. The reading of the message, however,

Digitized by Google

will always depend upon the condition of the atmosphere, and no message could be read unless the clouds are well defined and low.

Ship Lighting.—The electric lighting plant of the Great Eastern Railway Company's twin screw steamship "Peterboro," which left the Earle's Shipbuilding Company's yard at Hull on Friday, the 25th ult., consists of a compound-wound Phœnix dynamo, driven with rope gearing by one of Messrs. Alex. Shanks and Son's 6 horse-power Caledonian engines. The 100 16 candle-power 50-volt Swan-Edison lamps are arranged in four parallel circuits, and controlled by main switchboard in engine room, each light also having its own combined switch and cut-out. The pendant and bracket fittings are of new and graceful designs, those in the saloon and state rooms being silver-plated, and in the officer's and second class cabins burnished brass. The ship is also provided with gangway lights, consisting of clusters of lamps in enamelled reflectors, with lowering and raising gear for use when embarking passengers at night. The work has been carried out by Mr. Robert Woodley, electrical engineer, of 248, Burdett-road, London, E., who has recently completed similar installations on the new Wilson liners "Colorado" and "Apollo," and also an extensive arc lighting installation at Messrs. Earle's shipbuilding yard and engineering works.

Shotfiring by Electricity in Mines.—On Saturday, 19th Nov., some experiments were made in the Ynishir Colliery (near Cardiff) on the use of electricity for blasting purposes, in the presence of a large number of representatives of the mining industry. The interior of the mine, for some distance from the bottom of the shaft, was illuminated with incandescent lamps. Holes had been bored in the rock at distances apart of about 20 yards. They were then charged with dynamite, and the fuse and electrical connections having been adjusted, the hole was stuffed with clay. All the visitors and workmen then left the pit, and returned to the surface. The current was then switched on from the dynamo room, and the charge exploded. On entering the mine, it was found that all the charges except one had fired, and the result was considered exceedingly satisfactory, the single unexploded charge being due to a break in the connections. This unexploded charge was then fired while the party remained underground. The explosion dislodged a large quantity of material from the roof. After once more reaching the surface, the miners' representatives unanimously passed a resolution cordially congratulating the proprietor and manager of the Standard Colliery, Ynishir, on the results of the experiment.

The Vienna Breakdown.—We have received from a trustworthy correspondent in Vienna the following additional information on the above subject:—"The boilers which caused the recent failure of the Opera House installation were of a type known as Captain Scott's patent, and the arbitrators appointed in Vienna to consider the causes of failure, and at whose door the blame for the breakdown was to be laid, have found defects in the design of the boilers, and also attribute the failure to the water used. As this matter is, however, still *sub judice*, it would be unfair to comment further upon it. The temporary interruption of the lighting itself, however, seems to have been caused by official interference. Considering that four boilers were provided for the opera lighting, and of these three were available for the purpose, there seems no pressing reason why the exchange of the boilers could not have been effected without interrupting the lighting. The Imperial Continental Gas Association have, however, made the best of the matter, and have with the utmost energy, and in a remarkably short time, succeeded in putting up two huge goods locomotive boilers and resumed the lighting of the opera on the 19th Nov. A new battery of boilers has now been ordered of the Babcock and Wilcox Company, of Glasgow, who have undertaken to guarantee their efficient working. As regards the absurd rumours which have obtained currency that the cables proved bad, they are utterly without foundation, as a recent test of the cables showed a much higher insulation resistance than had been specified. Most of the reports from local sources were undoubtedly coloured by the jealousy of those electricians in Vienna who would have liked to have had a hand in the matter, which, in spite of the numerous difficulties encountered —some of which were put in the way—must be admitted to have been carried out, so far, at least, as the electrical details are concerned, in a most praiseworthy manner."

Telephonic Communication at Sea.—Mr. H. F. Boyer, of H.M.S. "Malabar," has recently made a number of experiments in this direction with an apparatus of his own invention. Previous attempts of the same general character by some American electricians were described in our issues of Oct. 7 and Nov. 4. The following description is given of the arrangement:—The source of sound consists of a large gong or flat bell supported against the side of the vessel below the water line. A straight tube leads from this gong to the "bridge" of the ship, and in its interior is a rod fitted with a handle at its upper end, by which the hammer of the gong can be worked, and the gong struck at will. The striking of the gong may, of course, be done in keeping with a code of signals, such as the Morse code used in ordinary telegraphy. In the centre of the gong is fixed a modified Bell telephone with a large and sensitive diaphragm. The telephone is connected by means of wires running up the tube to a second telephone on the bridge within reach of the observer there. This forms the receiving part of the apparatus. If we suppose two ships fitted with this combination, it is only necessary for one to rap out her message by striking the gong and for the other to receive it on her telephone. The sound waves from the transmitting gong traverse the intervening water and vibrate the diaphragm of the submerged telephone at a distance. These vibrations excite currents in the latter, which, in traversing the second or observing telephone, reproduce the original sounds of the gong. Small explosions of gun cotton under water have also been used by Mr. Boyer in place of the gong; and an ounce of gun cotton can in this way give a signal which is distinctly heard a mile off under water. Such signals under the sea are independent of fogs or stormy weather; and they hold out the possibility of lighthouses and lightships being able to signal vessels at all times. Moreover, ships, in addition to signalling each other, could also signal lightships, or announce their number to Lloyd's stations, if the system prove successful. Mr. Boyer's plan, which so far has given encouraging results, is somewhat similar to that of Prof. Lucien J. Blake, of the Rose Polytechnic Institute, United States, which was described in our issue of November 4th. Instead of a submerged telephone, however, it will be remembered that Prof. Blake uses a microphone in circuit with the deck telephone as a receiver. With this arrangement Prof. Blake has been able to transmit subaqueous signals from a locomotive bell through a mile and a-half of the Wabash River comprising three or four windings. Mr. Edison also is reported to have signalled through a mile of the Caloosahatchie River in Florida during the present year. His system has not been fully disclosed, but it appears to be similar to those described. It is to be hoped that this new development of telephony will be pushed as far as possible.

MOTOR-GENERATORS.

THE PARIS AND SCOTT SYSTEM.

This week we are enabled to reproduce photographs and sectional drawings of the Paris and Scott motor-generator which recently underwent some tests at the Newcastle Exhibition (see *Electrician*, October 28th, 1887).

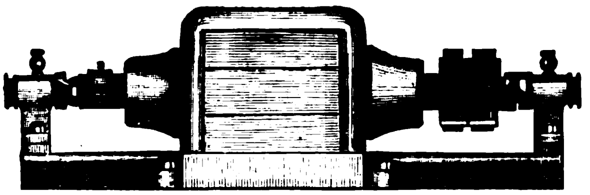

FIG. 1.—Side view.

We have little to add to the description then given, except that the mechanical details of the construction will be perfectly

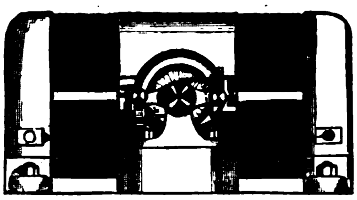

FIG. 2.—End view.

clear from the drawings. Fig. 1 is a side view, Fig. 2 an end view, Fig 3 is a cross section taken through the centre, and

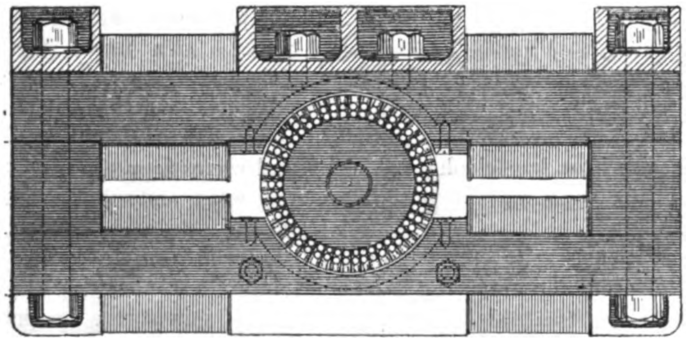

FIG. 3.

Fig. 4 a section at right angles to that of Fig. 3, the two latter being on a somewhat larger scale. In Fig. 4 P P is the primary

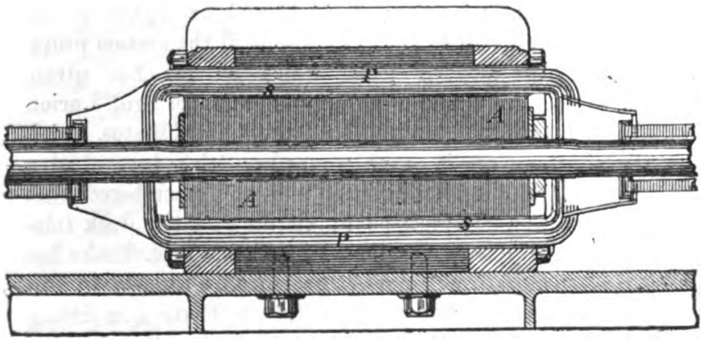

FIG. 4.

coil, S S the secondary, and A A the core, built up of iron discs.

The core of the drum is 12in. long by 5in. diameter, and each commutator has 45 sections, there being two turns per section for the secondary low-tension circuit (right-hand commutator), and eight turns per section for the primary high-tension circuit (left-hand commutator.) The electrical details of the machine were fully discussed in our issue above referred to. The normal speed of this machine is 1,200 revolutions.

Messrs. Paris and Scott, however, inform us that they are "now enabled to make transformers to run at much higher speeds with perfect safety, so that their efficiency and output can be very considerably increased." Perhaps the most satisfactory feature of this design is that the self-induction coefficients of the two armature coils practically neutralise one another, and there is absolutely no lead and practically no sparking on the brushes.

THE JEHL AND RUPP SYSTEM.

The adjoining illustration, which is taken from a photograph in our possession, shows the external appearance of the Jehl

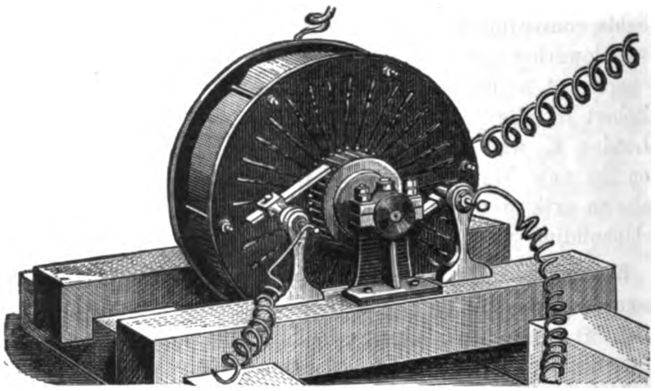

FIG. 1.

and Rupp motor-generator of the double ring type, as described in our articles of October 28th and November 11th. The

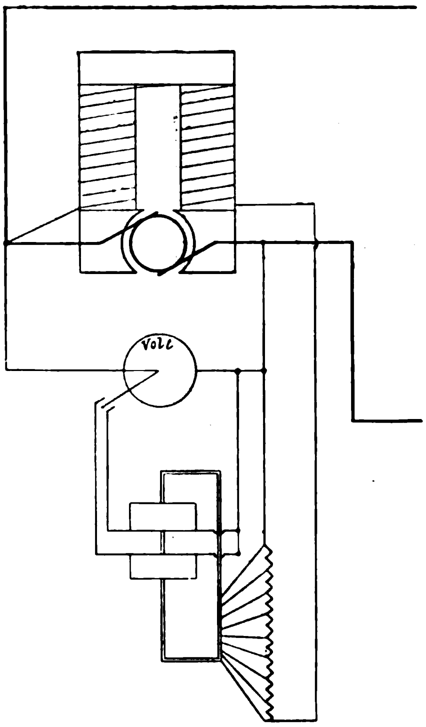

FIG. 2.

primary high-tension commutator is visible, the secondary low-tension commutator and the pulley from which the apparatus is driven are on the other side. Fig. 5 shows the latest type of the "distribution commutator." This apparatus has been much simplified and improved since we first described it. The necessary length has been reduced to one-fourth by the device of cutting each ring into four equal portions, and so making it

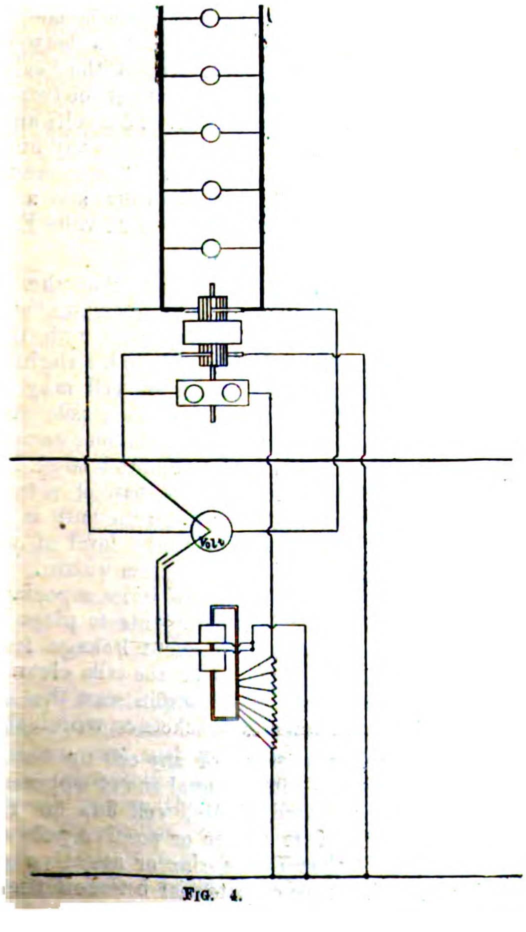

Fig. 4.

serve for four coils instead of one. The ordinary commutator on the left-hand side, which takes the high-tension current of 10 or 12 amperes, will serve to scale the apparatus.

We now conclude our account of the system by giving diagrams of the circuit connections for parallel distribution. Fig. 2 shows the generating dynamo with regulator for constant potential, as described in our last issue. Fig. 3 is a sub-station, provided with a $\frac{1}{4}$ H.-P. motor (*c*) driving a distribution commutator. In this case it is essential that the speed of the motor should be constant, and for this purpose (as the load remains the same) a regulator of the same type is employed. Only one motor-generator of the stationary type is shown connected to the distribution commutator; but it will have been understood already that there might be any number, having their corresponding coils connected in parallel. Fig. 4 shows

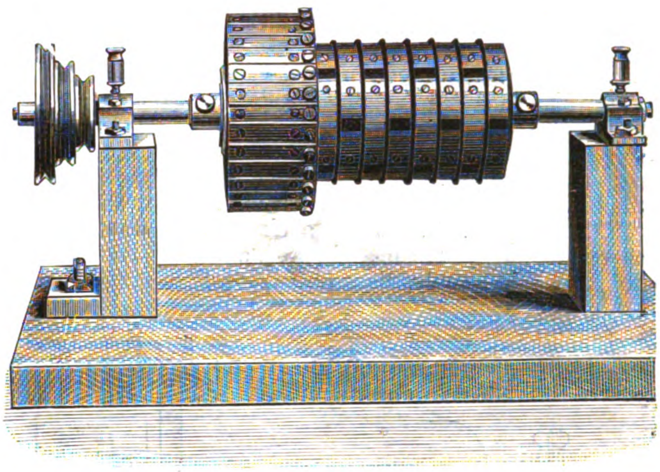

Fig. 5.

the connections for a single motor-generator of the automatic type.

Chapter III.

Batteries.

(Continued from page 53.)

19. Another type of cell in very general use for discontinuous work is the Leclanché. This is a single-fluid cell in

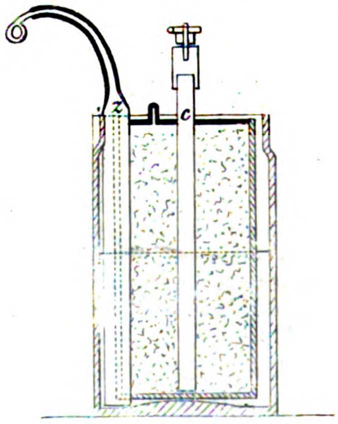

Fig 6.

which zinc is the positive element (*see* para. 8), carbon the negative, and a solution of salammoniac the exciting liquid. The carbon plate is surrounded by crushed carbon in intimate

Digitized by Google

admixture with black oxide of manganese, either by being inserted into a porous jar with those materials, or in what is called the agglomerate cell, by having those materials solidly cemented round the carbon plate in a cylindrical form under pressure. The zinc element is generally in the form of a rod, placed in one corner of the cell, which is represented in section at Fig. 6. During the cell's action the salammoniac, which is a compound of ammonia and chlorine, is decomposed, the chlorine attacks the zinc forming zinc chloride, which, being soluble, disappears into the solution, while the ammonia developing at the surface of the carbon also forms a soluble compound with oxygen, which it seizes from the oxide of manganese. Thus, in action, the zinc is consumed, its chloride accumulates in solution, the carbon is unaltered, and the oxide of manganese loses some of its oxygen. Practically, however, when the supply of current from the cell exceeds a certain rate, and consequently when the chemical decomposition reaches a certain degree of activity, the above simple set of reactions is not strictly carried out, secondary and more complex chemical products form, which soon culminate in the development of hydrogen at the surface of the carbon plate, and polarisation (*see* para. 10) sets in, unless resting time is allowed for the secondary products to dissolve. For this reason the Leclanché cell is not suited for strong and continuous current supply, and its E.M.F. (*see* para. 4), normally about 1·48 volts, soon falls under hard work. For more limited, and especially for intermittent current supply, however, the cell has many advantages.

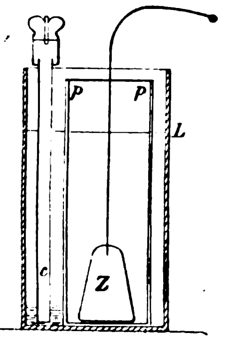

Fig. 7.

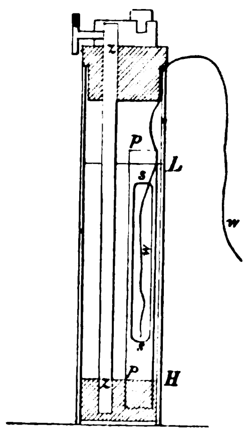

Fig. 8.

Its internal resistance is generally between 2 and 5 ohms, and can be made much lower if with this object the cell be heated. It requires very little supervision, and when engaged on light work, such as the occasional ringing of bells, will not unusually continue to operate for two years without any attention or recharge. If the zinc rods be of good material, there is also exceedingly little local action.

20. Fuller's bichromate cell is another single-fluid form of the zinc-carbon combination. The outer cell is a stoneware jar, as shown in section at Fig. 7. In it stands the carbon plate C, and the porous pot *p p*, filled with water to the level L, and holding the zinc plate Z, which is usually of conical form, and kept permanently amalgamated by dipping into mercury placed for that purpose at the bottom of the porous cell. The solution for the outer jar is of bichromate of potash in water acidulated with one-ninth of its volume of sulphuric acid. During hard work polarisation takes place to some but not as a rule to any serious extent, and the E.M.F. of the cell is approximately 2 volts, and its internal resistance from about 2 to 5 ohms.

21. A very convenient and portable form of cell for testing and light signalling work is De la Rue's single-fluid chloride of silver cell, represented in section at Fig. 8. The outer cell is a glass tube one inch in diameter, with a flat bottom. It contains a solution of 200 grains of salammoniac to the pint of water, and the elements are zinc and silver. The latter is in the form of a wire, *w*, fused into a cylindrical mass of chloride of silver, which is further protected by a paper tube, *p p*, to keep it from coming into contact with the zinc rod, *z z*. If set up with care, and not subjected to very hard work, the E.M.F. of this cell is remarkably constant at about 1·03 volts, and the average is so well maintained by different cells that in the absence of a standard of E.M.F. more accurate, it may be generally relied upon for that purpose to a limit of 1 per cent. when comparing measurements made at different places. Its internal resistance in good order is from 1½ to 5 ohms. The dimensions of the plates prevent the use of these cells for hard work, as the zinc would soon be entirely consumed; but they take up so little space, are so easily insulated, and once carefully set up require so little attention, that they are admirably adapted for testing and signalling, particularly on board ship. As the zinc should never touch the paper tube in the cell, it is a good plan when setting up the latter to first pour in melted paraffin wax to the height (H, Fig. 8) of about half an inch, and then lower the elements into their proper opposite positions, so that they remain fixed at their lower ends as the wax solidifies. It is also well in order to prevent corrosion to whip with silk the external loop of silver wire which connects cell with cell.

22. A cell which is most useful in testing, but which is used almost solely for the purpose of supplying a reliable standard of E.M.F., is the Clark standard cell. This is a combination of pure zinc and mercury, and its E.M.F. is 1·45 volts at 66° F., diminishing very slightly as the temperature rises. This E.M.F. is very constant, and the amount of its variation between different cells is generally exceedingly small. To maintain its constancy this cell should never be allowed to send a strong current. Its internal resistance is therefore immaterial; but as it tends ultimately to increase enormously with age through the drying up of the exciting salts, it is necessary to ascertain when employing the cell that its resistance is not excessive.

23. The usual mode of connecting any number of cells together to unite their powers is by joining the positive pole of one cell to the negative of the next all through the series. The E.M.F. and resistance between the terminal poles of the battery so formed will be the sum of the E.M.F.'s and resistances of the individual cells. Thus, if the zinc pole of a Fuller cell, whose E.M.F. is 2 volts and resistance is 3 ohms, be connected to the carbon pole of a Leclanché, whose E.M.F. is 1·5 volt and resistance is 5 ohms, then between the carbon pole of the Fuller and the zinc pole of the Leclanché respectively—the positive and negative poles of the two-celled battery so formed—there will be an E.M.F. of 3·5 volts and a resistance of 8 ohms. Similar reasoning applies to any number of cells. So that if we connect up *in series*, as it is termed, 20 Daniells, each having an E.M.F. of 1·05 volts and a resistance of 10 ohms, we shall obtain a battery of 21 volts E.M.F. and 200 ohms total internal resistance.

24. It is important to remember that the necessity for improving the insulation of cells increases with the total E.M.F. accumulated, or, in other words, with the number of cells connected in series. For although a slight film of moisture on the outer surface of a glass cell may only allow an inappreciably small current to pass from pole to pole of that cell singly, the loss of current may become serious when that leakage may form the path of escape to a large E.M.F.; in the same way that a small leak at the base of a tank may cause only a trifling escape of water when the tank is nearly empty, but might allow of serious loss as the level of water and consequently the pressure is raised from within. It should be the object, therefore, with large batteries, especially when they are employed in delicate measurements, to place them on insulating supports, and also to prevent leakage from cell to cell by keeping the outer surfaces of the cells clean and dry. A good method is to coat with paraffin wax the outer surfaces of the cells and the trays or brackets on which they stand.

25. As long as the poles of any cell or battery are insulated their potentials will be equal and of opposite signs. For example, if an insulated Daniell cell has an E.M.F. of 1·08 volt, the potential of its copper or positive pole will be 0·54 + or positive, and that of its zinc or negative pole 0·54 – or negative, the difference of potential between them being thus

Digitized by Google

1·08, equal by definition to the E.M.F. Similarly with an insulated battery of 100 volts E.M.F., the potential of the positive pole will be + 50, that of the negative pole − 50. Consequently if the battery be homogeneous, the potential at its centre must be zero. This zero potential is really the potential of the earth and of all neighbouring conductors in connection with it. So that like the effect of the moon's gravitation on the ocean, which produces in the tides a fluctuation of level above and below the normal level of the sea, the effect of the contact of the different metals of a cell, either singly, or as accumulated in a battery, is to produce at the insulated poles potentials equally deviating above and below from the potential of the earth, which, being constant, is reckoned as zero. So that when we speak of potential we tacitly refer to this earth potential zero, but no such allusion is necessarily made when we discuss difference of potential, viz., E.M.F.; just in the same way as when we speak of the level of a position as being 3,000ft. high, we refer it to the mean level of the sea, while difference of elevation is an idea in which the sea level may have no part.

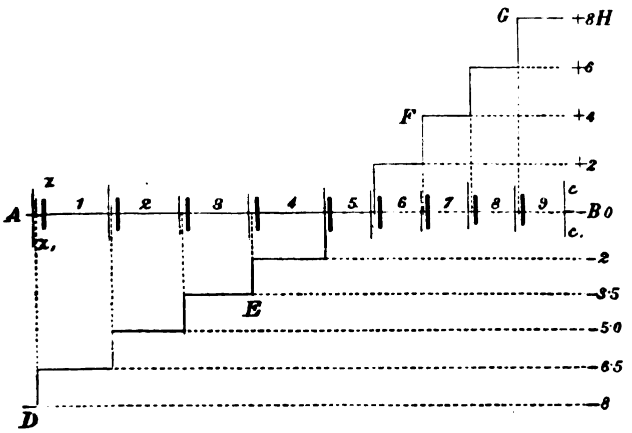

Fig. 9.

26. Fig. 9 shows how we may graphically represent the rise of potential in an insulated battery. The thick lines similar to *z z* across the dotted line A B represent the zinc plates, and the thinner lines similar to *c c* the copper or carbon plates of the battery. Now, holding up the paper so that its plane is vertical, the upright lines similar to A D represent in length and direction the potential in the battery at the points on

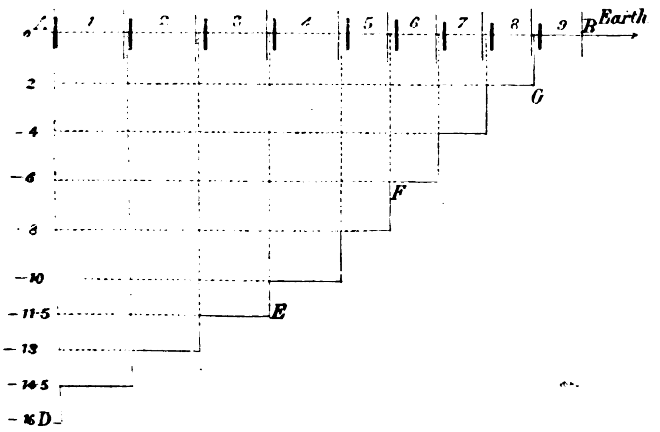

Fig. 10.

which they rest. Positive potentials are represented by lines above A B, negative potentials by lines below. Suppose we take a scale of measures such that a difference of potential of one volt shall be represented by one-eighth of an inch. As we may select any horizontal scale we please, it will be convenient to make it correspond to the internal resistance of the battery, and our diagram will then embody both E.M.F. and resistance. Let us take a horizontal scale along the line A B of 8 ohms to the inch. Now let us consider the case of an insulated battery, A B, of nine cells, numbered as shown, the first four being Leclanché's, each of 1·5 volt E.M.F. and 3 ohms resistance, and the last five Fuller's, each of 2 volts E.M.F. and 2 ohms resistance. Then the total E.M.F. will be 16 volts, and resistance 22 ohms, so that the latter will be represented on our scale of 8 ohms to the inch by placing the poles of the battery $\frac{22}{8} = 2\frac{3}{4}$ inches apart, so that the line A B must be $2\frac{3}{4}''$ long. Each cell may now be marked off along this line, the distance from one connection to the next being $\frac{3}{8}''$ for the Leclanchés and $\frac{1}{4}''$ for the Fullers. The plates may then be sketched in their right positions, as shown. The vertical scale has now to be considered. We have seen in the preceding paragraph that the points A and B will receive equal and opposite potentials, each equal to half the total E.M.F., which in this case is 16 volts; consequently, B being the positive pole will have a potential of + 8, represented on our scale by a point one inch above A B, while the negative pole A will have a potential of − 8, indicated by the point D one

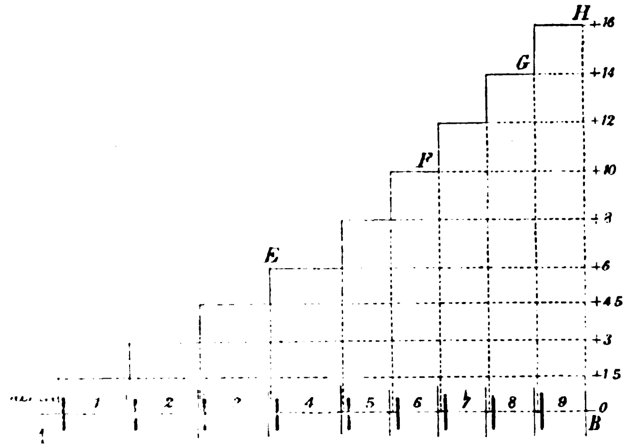

Fig. 11.

inch below A. By then carrying horizontal lines from D and H parallel to A B, and altering the potential opposite each junction of plates by the exact amount of E.M.F. that junction generates to scale, we shall produce the zigzag line D E F G H, every point of which represents by its distance from A B the potential of the point opposite to it in the battery.

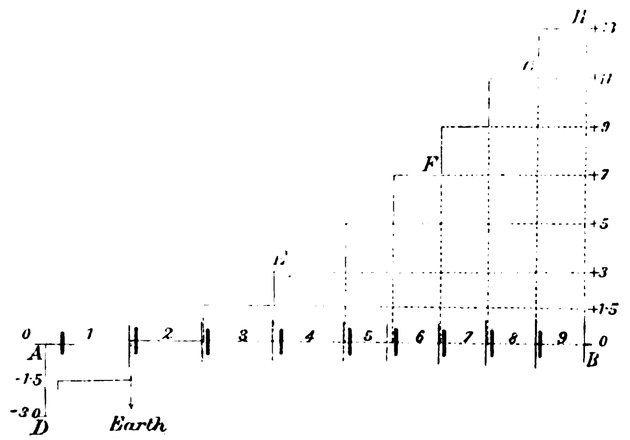

Fig. 12.

27. In the particular case of the battery we have considered, we see from the figure that the potential line in the first Fuller cell, No. 5, coincides with the line A B, and since A B is also, as explained in paragraph 25, the earth potential or zero line, the potential of cell No. 5 must be zero. Consequently, the potential line D E F G H will not be disturbed if this cell be connected with the earth by dipping a wire into it whose other end is deeply buried in the ground, for example; for by so

Digitized by Google

doing we simply connect two bodies at the same potential, and no current tends to flow under ordinary circumstances between two bodies at the same potential any more than water tends by gravitation to flow between two points at the same level.

28. If, however, the earth wire be removed from cell No. 5, and connected to any other point in the battery, the position of the line of potentials will undergo alteration. For example, if the earth wire be connected to B, the positive pole, as in Fig. 10, a current will tend to flow from B to earth, but cannot be maintained because it can find no circuit, the battery being otherwise insulated. The point B and the earth cannot, however, retain different potentials after connection, so B's potential falls to zero. But the mere connection of B with earth cannnot alter the E.M.F. of the battery—that is to say, cannot alter the difference of potential existing between the poles A and B; so that as B has lost a potential of 8, A must be augmented by that amount, and will therefore become − 16, as shown, and filling in the sections of the potential line as before, we find that it has descended bodily from its previous position through the distance H B. Similarly, if B be insulated, and A instead earthed, as in Fig. 11, the potential of A becomes zero, that of B makes up for the loss by becoming 16, and all other points retaining their relative potentials to these the potential line is moved bodily up to the position shown. Again, Fig. 12 shows the effect of putting to earth a particular point in the battery otherwise insulated. We thus see that in all cases of connecting to earth, the potential of the point earthed is brought to zero, and the potentials of all the remaining points in the battery follow from this point by the simple summation of the individual E.M.F.'s as they are met with.

REVIEWS.

A Handbook for Steam Users: Being Rules for Engine Drivers and Boiler Attendants, with Notes on Steam Engine and Boiler Management, and Steam Boiler Explosions. By M. Powis Bale, M.I.M.E. (London: Longmans, Green and Co, 1887.)

It is much to be hoped that reservation of all rights in this book will be strictly observed by book makers and paragraph writers, for it is not very likely that any copyist will escape selecting some of the many statements that should be avoided. It is possible that the book may be of use to some amateur engineers who are owners of boilers, for a small amount of education will enable them to check the statements it contains, while the mere mention of some points in connection with boilers and boiler working will be sufficient to prevent their being forgotten—that is to say, the book may act as a mere reminder. For steam users generally it is not, however, of any use, nor can it be to the ordinary run even of the most intelligent boiler or engine attendant, but will rather lead them astray on many points.

It is not advisable to tell an engine attendant that "a little fine-powdered plumbago or asbestos may be added with advantage, especially to the cylinder lubricator;" nor that "where there is a constant surplus of steam for the work to be done, instead of damping down and working at a lower pressure, the author prefers in many cases to keep steam up to the full pressure and to shift the excentric sheave so that the slide valve will cut off earlier and expand the steam to a greater extent." The consequence of following the first of these suggestions, except in the most careful manner possible, will be to fill lubricating channels or grooves in bearings and stop lubrication, and to fill clearance spaces, and do a great deal more harm than good. The second suggestion shows an almost incomprehensible ignorance of the working of steam boilers, and of the effect of moving an excentric. Firstly, a constant surplus of steam does not in the least degree make it possible to work the engine at a lower pressure; secondly, if there is a constant surplus, that may equally be the case of working at a low or at a high pressure; thirdly, it would be much better to maintain the proper pressure and work with a smaller fire; and, fourthly, if an engine attendant shifts the excentric so as to cut off earlier he will also admit steam much earlier, and if the cut-off is to be materially affected the lead will become so excessive as to make the engine work very badly, if at all, and with great loss; fifthly, the average attendant will make a muddle of it if he shifts the excentric at all; and, sixthly, the tendency would, if successful, be to use less instead of more steam.

Again, it is not advisable to tell an attendant who has a troublesome pump that "occasionally a valve that has struck may be released by a few sharp blows of a hammer on the outside of the clack cover." It is of no use to a boiler attendant to tell him, without any explanation, that "in cases of urgency steam may be 'whitewashed' by turning the exhaust or a jet of steam into a base of the chimney-stack." It is useless to tell a traction engine driver that "for travelling he is to get steam up to 75lb. pressure." Engine and boiler may both be made to work at 100lb., and for some travelling the driver may want all this, and it is nonsense to tell him that "when going down a hill the gauge glass should show 4in. of water, when going up about 1in." When "working boilers and engines in frosty weather" the attendant is told, amongst other very wise things, that he should "in very frosty weather have the flywheel of the engine barred or turned round by hand a few times in case of ice being in the cylinder." After writing this it probably occurred to the author that it might not work, so he tells the attendant to "thoroughly warm the cylinder before starting."

He might therefore have saved the attendant the trouble of barring the fly-wheel round before warming the cylinder, unless he thought of crushing the ice so quickly that the thermal equivalent of the work done would sufficiently raise the temperature. In telling the steam user how to find the necessary size of a factory chimney, he misquotes a rule given in "Modern Steam Practice," by Mr. J. G. Winton, and for a chimney 80ft. in height, for a Cornish boiler of 40 nominal horse-power, gives an area in inches of "539, say 26in. diameter, or 23 square inches at the top." This latter will puzzle the boiler user.

Enough has been said, perhaps, to show that this book needs revision or suppression; but we must mention that according to the author's rule for the nominal horse-power of engines, the addition of a condenser to a non-condensing engine of, say, 90 nominal horse-power, reduces its power to about 35 horse-power!

INCANDESCENT LAMPS.—A NOTE ON THE CONDUCTIVITY OF GLASS.

BY NELSON K. CHERRILL.

Prof. Ayrton, in his "Practical Electricity," page 271, says that the resistance of dense flint glass increases very rapidly as the temperature diminishes below 60° C. From this it might perhaps be inferred that the resistance might be expected to diminish as the temperature rose above 60° C.

My attention was first directed to this subject some two or three years ago by noticing a very curious and persistent fault in a number of incandescent lamps under my charge at the time. One of the platinum wires of these lamps was almost invariably blackened where it passed through the glass. For a long time this defect was attributed to careless manipulation on the part of the glass blowers; it was thought they had not taken care to see that the wires were really clean when put into the glass. This possible cause of the failure having been eliminated without affecting the result, I was led to note that the blackened wire was always on the same side relatively to the arrangements for supplying current to the lamps during the pumping process.

This led to the idea that perhaps glass was not, after all, under certain conditions, such a perfect insulator as was usually supposed.

A soft rich lead glass was being used for the manufacture of the bulbs at that time, and I found that—especially after recent working—a very moderate rise in temperature produced such a fall in resistance that a very appreciable amount of current would pass through the glass, the glass between the platinum wires acting as a shunt to the carbon of the lamp during exhaustion. This led to the supposition that the blackening of the wires was caused by a deposition of lead from electrolysis of the glass.

The current used had an E.M.F. of about 100 volts.

I tried the resistances of the glass between two platinum wires,

Digitized by Google

sealed in in the ordinary manner, but without any carbon filament, and I found that immediately after sealing in—that is, as soon as the bulb was cold—the resistance did not amount in many cases to more than 15,000 ohms, but the next day it had risen enormously higher.

When, however, the glass was reheated to only a moderate extent—that is to say, far below its melting point—the resistance was very largely decreased, to be again increased on cooling; but, according to my observations, the full or normal resistance is not attained—at any rate, with lead glass—for many hours after the glass is cool. It would seem as if some action of crystallisation goes on in the glass, even after cooling, which changes the molecular arrangement.

Lead glass is not peculiar in exhibiting this property of becoming, to a very appreciable extent, conductive under the influence of moderate heat.

An interesting experiment can be tried with a very small battery and galvanometer by simply fusing a bead of glass upon a wire, and inserting a second wire into the bead, making up the circuit so that the current passes through the glass. I used one cell of Leclanché's battery and an ordinary astatic galvanometer, with a bead of glass about the size of a small pea; the needle of the instrument flew to its stops as soon as the bead, held in the blow-pipe flame, assumed the faintest redness. By manipulating carefully the bead can be drawn out, and the effect on the galvanometer may be noted at the same time; in this manner I got a clear deflection of 10deg. of the scale through a filament of glass three-eighths of an inch long without only three cells of battery. Hard German glass behaves just in the same manner. I have tried many kinds of glass and they all give the same result.

There is one point in connection with this matter which may be worth consideration. Glass is usually looked upon as a *solid* substance, and it is certain that at the temperature at which the electrolytic action I have referred to in the manufacture of lamps took place the glass was far from being in a "plastic" condition; and yet in a solid substance we have here a movement of the constituent molecules into new positions, called, I think, in electrolysis "the migration of ions," the "solidity" of the material being maintained all the time.

ON THE CONDUCTIVITY OF AMALGAMS.*

BY C. L. WEBER.

The author points out that up to the present no complete and concordant results have been obtained on the resistances of a series of amalgams of varying percentages of added metal.

A considerable difficulty in such an investigation is that between the amalgams so poor as to be perfectly fluid and those so rich as to be perfectly solid there lie those of medium richness, which at ordinary temperatures are neither the one nor the other. These do not remain homogeneous when standing, but separate into layers varying in solidity and richness, and when the resistance of such amalgams is measured the result is the mean resistance of these varying layers, and not that of the homogeneous amalgam.

In order to avoid this source of error the author's measurements were made on amalgams at a high temperature, so as to have them perfectly fluid and homogeneous. Preferably the temperature was above the melting point of the added metal, but this was only possible in the case of bismuth and tin. In the case of lead and cadmium the temperature could not be taken high enough with satisfactory results. The tin amalgams were tested at (about) 240deg. C., those of Bi Pb and Cd at (about) 265deg. C. These temperatures were maintained as accurately as possible, and a few degrees too high or too low would have no appreciable effect on the results, as the temperature coefficients of the amalgams were very low. At 265deg. all the alloys of Bi were liquid, and for Pb and Cd all those up to 70 per cent. added metal.

There is no doubt that working in this way far more light should be thrown on the effect of chemical composition *per se* on the resistance than when solid amalgams or alloys are used,† for structure, which has so large an influence on the behaviour of the latter, is completely eliminated. The resistances were measured on a Thomson bridge. The alloy was in a U-tube with enlarged ends, heated in a paraffin bath. The tube was closed with corks, through each of which was passed an iron wire electrode and a glass tube. By alternately blowing and sucking at one of the tubes the amalgam could be thoroughly agitated from time to time, and kept perfectly homogeneous.

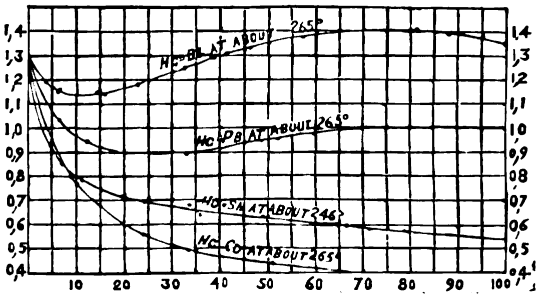
The results obtained are plotted in the curves shown.

Mathiesen, it will be remembered,‡ working with solid amalgams of Pb Cd Sn, &c., made the conductivity of the amalgam equal to the mean conductivities of its components, thus making the curves straight lines. Herr Weber's curves with fluid amalgams are anything but straight. Those for Sn and Cd drop very rapidly for the first small additions of added metal, and then appear to follow a straight line law, falling steadily to the resistances of these metals when pure.

The Bi curve also falls sharply for the first small additions, then passes through a minimum and rises again, passes through a less accentuated but clearly marked maximum, and then falls to the pure metal resistance. This amalgam, it is interesting to note, has at one percentage a *higher* and at another percentage a *lower* specific resistance than either of its components.

In the case of lead, the mininum is equally well marked, and the resistance also falls below that of either component. The amalgams beyond 70 per cent. of lead could not be tried, so that a maximum similar to that obtained for Bi could not be got; but the author thinks that an inspection of the curve as far as it goes leaves no doubt that it would have occurred.*

That the maxima and minima indicate chemical compounds is highly probable. It will be noticed that they point to combinations represented by Hg_9 Bi, Hg Bi_3, and Hg_3 Pb, and probably Hg Pb_3. It is noteworthy that Pb and Bi, which behave alike, are also near



together in atomic weights, viz., 207 and 210. And that Sn and Cd are likewise similar in curve, and atomic weight 212 and 218.

[True; but then Bi and Sn, which are *closest of all* in atomic weight, are the most *un*like in their behaviour.—ED. *E.*]

* De la Rive gives (*Comptes Rendus*, 1863, p. 698) specific resistance of pure melted lead at 358deg. as 1·04; at 265deg. it would be less, and well below the last point on the lead curve.

MEETINGS OF SCIENTIFIC SOCIETIES.

(Week ending Thursday, 8th December.)

TO-NIGHT, Friday, December 2nd.

INSTITUTION OF CIVIL ENGINEERS.

7 p.m. Paper, "On the Classification of Continuous Railway Brakes." By Mr. A. WHARTON METCALFE.

7:30 p.m. Students' Meeting.

SATURDAY, December 3rd.

PHYSICAL SOCIETY (South Kensington, *3 p.m.*).

MONDAY, December 5th.

SOCIETY OF ENGINEERS.

Paper, "On a New Formula for the Flow of Water in Pipes and Open Channels." By Mr. E. C. THRUPP.

SOCIETY OF ARTS.

8 p.m. Cantor Lecture Series.—I. "The Elements of Architectural Design." Second part. By Mr. H. H. Statham.

TUESDAY, December 6th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper, "On the Bessbrook and Newry Tramway." By Dr. E. Hopkinson, M.A., &c.

WEDNESDAY, December 7th.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting.

THURSDAY, December 8th.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS (at the Institution of Civil Engineers).

8 p.m. Annual Meeting for reception of Report and Election of Council and Officers. A Paper, "On Safety Fuses for Electric Light Circuits, and on the Fusing Points of various Metals Employed in their Construction," will be read by Mr. ARTHUR C. COCKBURN, F.C.S., Associate.

ROYAL SOCIETY.

4:30 p.m. Ordinary Meeting.

*** Particulars of meetings to be held or papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial and Publishing Offices:
No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.
Telephone No. 2714.

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* THE PROPRIETORS.

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at Messrs. Smith and Sons' railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.*

The rates of subscription to "THE ELECTRICIAN" *(including postage) are as follows:—*

	3 months. s. d.	6 months. s. d.	12 months. s. d.
For the United Kingdom	4 11	9 9	19 6
,, Foreign Parts and Colonies:— Within Postal Union	5 6	11 0	22 0
,, Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	6 1	12 1	24 2

"The Electrician" in America.

"THE ELECTRICIAN" *can be obtained in America from* D. VAN NOSTRAND, *23, Murray-street, and 27, Warren-street, New York.*

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December next.

The EDITOR *will be glad to receive new names for insertion in the* DIRECTORY *as soon as possible, but not later than December 1.*

All particulars relating to Advertisements will be at once forwarded, on application.

VOLUME XIX.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

Office: 1, SALISBURY COURT, FLEET STREET, LONDON, E.C. (Telephone No. 2714.)

INVENTORS AND PROMOTERS.

Some recent judicial pronouncements on the obligations between promoters of companies and shareholders are likely to have a very wholesome effect on the business relations of these parties. Anything that is calculated to inspire the public with confidence, and the promoter with caution, cannot fail to facilitate the flow of capital into legitimate channels, and to lessen the difficulties of obtaining it for sound investments. Actions for fraudulent misrepresentation in a prospectus of a limited liability company have latterly become quite common, the law on this point being now made pretty clear. But until the other day the question whether misrepresentation, not fraudulent, constituted a ground for rescinding a contract between inventor and promoter was by no means so certain. Mr. Justice KAY, in the Chancery Division, last Thursday, laid it down that in order to constitute a defence to an action for breach of contract it was not necessary to prove fraudulent or intentional misrepresentation in respect to the original contract; it was sufficient if the misrepresentation was real and material, even though quite innocent in its character. The defendant could on such ground get the contract rescinded; and it necessarily followed that the plaintiff could not obtain damages for the non-fulfilment of such contract.

The action which gave rise to this judgment was brought by Messrs. ELMORE, carrying on business as the Electro-Metallurgical Company, against Messrs. TIMMINS and PIRRIE, agents for Messrs. BARRETT and RAWLINGS, who it was alleged had undertaken to bring out a company for working certain electrolytic patent processes invented by Mr. ELMORE, the sum of £15,000 and 25 per cent. on the capital to be paid the inventor. The promoters never started the company, alleging, among other reasons for not doing so, that the statements of Mr. ELMORE with respect to his processes were greatly exaggerated, and that, in fact, the patents were

Digitized by Google

worthless. There is no need for us to go into the merits of these allegations on one side or the other. The evidence, which extended over several days and was of the most conflicting kind, although seriously reflecting either on the memory or the veracity of the witnesses, failing to shake the main contention of the defendants, namely, that they had taken up the scheme on specific statements of the inventor with regard to the practical value of his patents, which proved to be inaccurate and misleading. This alone sufficed to destroy the plaintiffs' case, which was dismissed, but without costs, the Judge remarking that he was dissatisfied with the evidence adduced on both sides.

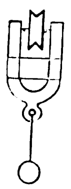
It seems to be plain, therefore, that any false or extravagant representation resulting in misleading one party to a contract, although that may not have been intended, will serve to void the contract in law. In other words, where an invention is concerned, the inventor must tell the truth about it to the proposed purchaser, and must carefully avoid telling an untruth even by accident, or he may find himself utterly unable to enforce the bargain. This is serious news for inventors, whose sanguine and imaginative temperament is always apt to lead them into fits of inexactness, and seldom fails to convince them of the truth of anything they wish themselves to believe. Perhaps we may rely, however, upon their inventiveness to steer them clear of this pitfall in future. The inventor may not be able to sell quite so easily as heretofore; but neither will his competitors; and if the market is limited to the sale of meritorious inventions, the price of the commodity will go up proportionately, and good men and true will get their own. To promoters we need add no word of warning or consolation. They can very well take care of themselves; and perhaps nobody would particularly regret their entire extinction. They have got the best of the inventor in the present action; let them take care that the public never get the better of promoters on a similar plea.

Commenting on this point an evening contemporary which is equally conspicuous—we had almost said equally notorious—for its own lofty morality and its base estimate of other peoples', is very severe on promoters :—"The wily promoter has so long fattened by the sale to companies, promoted for their purchase, of patents whose virtues mainly consist in their vendors' abilities to puff them, that Mr. Justice KAY'S decision will be generally welcomed." We trust it may; but the investing public have only an indirect interest in this action, and if they had been a party to it they would have got nothing by the decision, the parties to the suit being left exactly as they were before the action was commenced. On the other hand, when the public are concerned in a case of this sort they have paid their money and seek to recover it, an object they seldom succeed in accomplishing, whatever the verdict, seeing that the money has generally vanished with the hopes and promises on which it was staked. Possibly, however, the investor may now have a double chance of recovery, both inventor and promoter being clearly liable for misrepresentation. It seems to follow from the judgment in ELMORE *v.* PIRRIE that if a contract can be rescinded before it is completed, it can be rescinded after completion. That is to say, on discovery and proof of misrepresentation, shareholders could repudiate a bargain and claim back their money from the misrepresenting vendors. We should be sorry to say a single word to encourage purchasers to enter upon such a course of action; but it is well that they should know their remedy in future, and still better that inventors and promoters should be made aware of what they may expect if they obtain capital upon representations which are either wilfully or innocently false. The decision will tend to make all the parties more circumspect, more cautious, more accurate, and more conscientious towards each other, and in this way promote a confidence among them which at present is conspicuously absent.

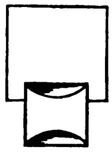
CAPT. CARDEW'S "STANDARD" VOLTMETER.

We are indebted to Captain Cardew for the following description of the "Standard" voltmeter, to which he briefly referred at the meeting of the Society of Telegraph-Engineers and Electricians on Thursday last :—

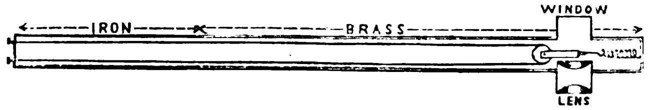
"The instrument consists of a tube made of very thin metal, two-thirds of the length being of brass and one-third of iron. This tube should be 2½in. to 3in. in diameter. About three inches from one end the tube must be cut open at two opposite sides to admit of a lens and a glass window being inserted in short pieces of tube of the proper dimensions, preferably by screwing them in. The lens should be a compound one, similar to the object glass or image-producing lens of a good magic lantern. It is better to use a large lens, and cut off the outside parts with a diaphragm. The lens should, of course, have a very short focal length.



Stirrup with ivory pulleys and cross hairs.



Lamp with converging lens.



Voltmeter Tube, &c.

The end of the tube near the lens is closed with a brass plate, to the centre of which is attached one end of a spiral spring of brass or German silver, formed of an equal number of right-handed and left-handed turns, so that the free end in moving up or down should have no motion of rotation. The other end may be conveniently closed with a piece of ebonite, having two terminals, to the end of the screw of one of which one end of the fine wire is carefully soldered, while the other end is attached to a screw passing through a brass collar screwed in or out by means of a nut and prevented from turning itself. This is connected to the other terminal. The fine wire should be ·0014in. diameter platinum silver. It should be obtained wound on a bobbin of large diameter, and in unwinding the bobbin should be rotated.

"The end of the wire is passed through the brass collar round a little ivory pulley held in a very light aluminium stirrup, and then soldered to the other terminal. The tube should now be held vertically, the ebonite cap put on, and the wire paid away very carefully. There should be a small weight hooked on to a short piece of rather stouter wire attached to the stirrup and carrying a small ring for hooking to. The lens, glass window and brass bottom to tube are all removed. The wire is paid away until the stirrup appears at the bottom, when it is held while the weight is removed and the end of spring hooked in. The brass base is then carefully brought into position, pulling up on the wire all the time and fixed with screws, which should pass through slits in the tube to allow of the brass base being rotated through a slight angle. The wire is now hauled up until the stirrup is above the proper position, when it is soldered and secured to the end of the adjusting screw, and the ebonite cap fixed in position. The cross hairs, which should be the finest spider webs, can now be fixed through the opening for lens, and the final

Digitized by Google

adjustments made. Great care is necessary in stringing not to get a twist in the two wires, and to have the plane of the hairs parallel to that of the lens. The lamp should send a powerful parallel beam through the window from a distance of some feet. The screen should be several feet away, depending upon the intensity of light used. In my case I use a whitewashed wall for screen, and have a beam compass fixed at a short distance from it, one pointer of which is illuminated by the beam, and casts a definite shadow on the wall, the point of which is made to coincide with the image of the hair. The hairs are about ¼in. apart, and the magnification is about 100 times. The object of the two hairs, as I explained, is to provide a base line. The images must be kept at a certain distance apart on the screen, then you have the assurance that a certain motion of the image means a certain elongation of the wire.

The chief constants of the instruments are :—Safe potential difference from 12 to 15 volts per foot with ·0014″ Pt. silver wire—thus for 100 volts total length of tube to pulley about 4ft. Cold resistance of wire about 90 ohms per foot. Variation for temperature about ·037 per cent. per 1deg.C. (This has been determined to red heat, but different samples vary slightly.) This has the effect of producing about an equal percentage decrease of reading for increase of external temperature. Elongation about ·04″ per foot, with 12 volts applied.

The tube should of course be placed horizontally to avoid the effect of convection currents, although these are barely perceptible with ·0014″ wire if a maximum of 12 volts per foot be not exceeded.

FINSBURY TECHNICAL COLLEGE OLD STUDENTS' ASSOCIATION.

THE DISEASES OF DYNAMOS.*

BY PROF. SILVANUS P. THOMPSON, D.SC.

Considering the wide-spread use of the dynamo-electric machine and the mass of literature concerning it that has sprung up, it seems remarkable that no one should as yet have written upon the topic of the maladies to which such machines are liable, their treatment, cure, and prevention.

Not once nor twice has it occurred in the writer's professional experience to be called into consultation over some hitch that has arisen in the maintenance of an electric light installation where the experience of the engineer and the knowledge of the electrician in charge had failed to discover the cause of the breakdown or suggest an appropriate line of action. Under such circumstances one cannot help comparing oneself to a physician called into consultation over a patient. And as a knowledge of the diseases of dynamos and their treatment form a necessary part of the complete training of the electric engineer an attempt by a specialist to elucidate the subject and systematise it, may appropriately be brought before such a society as this, comprising as it does many electrical engineers.

Moreover, as some of the members of this society have had large and diversified experience in the construction, erection, use, maintenance and repair of dynamos, the writer hails this opportunity of inviting an interchange of expression from all members present respecting the causes that lead to the breakdown of dynamos and their prevention.

The diseases of dynamos, like those of human beings, may be classified under several heads, whether constitutional or acquired, whether curable or incurable, whether surgical or medical in the treatment required.

The constitutional diseases may arise either from defective design or imperfect construction. A ricketty constitution in a dynamo may result either from inherent badness in the forms of those parts which should give strength to the structure, in the employment of bad or faulty materials, or in bad workmanship. Diseases acquired as the result of overwork and of neglect, though classified as acquired rather than constitutional, are more likely to be developed where there is a constitutional weakness. The physician who is called in must have the eye to detect the constitutional taint as well as the more obvious present causes of mischief. When called into consultation upon a human subject the physician's first inquiry is as to the symptoms that present themselves. Perhaps a clinical examination is necessary to learn the whole of the symptoms in the case. The diagnosis of the case being completed a course of treatment suggests itself, which course may be of several kinds. A surgical operation may be necessary, or perhaps bandages and poultices may accomplish all that is required. It may be proper to administer drugs; or in milder cases a change of climate or diet is all that is prescribed. Simple rest accomplishes wonderful cures; but in neglected cases long and careful nursing may be the only hope.

It may safely be said that at least four-fifths of the breakdowns that occur with dynamos—whether partial or total—arise from causes that are more strictly within the province of the engineer than in that of the electrician. On the other hand, many of the mechanical faults that develop themselves in the machine might have been avoided had the engineer possessed a better knowledge of the electric and magnetic conditions that obtain in the running of the machine. It is not often nowadays that armatures fly to pieces. That disaster has seldom occurred since good engineers took in hand the construction of dynamos, though it was, relatively to the number of machines used, a not unfrequent occurrence in the days when armatures were mostly designed by electricians who had little or no knowledge of mechanical engineering. On the other hand, any engineer will make a poor builder of armatures who does not understand the nature of the reactions that occur in the magnetic field—how a conductor carrying a current is subjected in the magnetic field to a mechanical force exerted upon it without any visible means of transmission. If he does not understand this he will not grasp the necessity of so designing and constructing the armature and its spindle that the power applied to the spindle shall be conveyed directly to drive the peripheral conductors. He cannot realise that it is the copper wire and not the iron cores that primarily require to have the power applied to them. He may know that insulation is necessary, and that lamination of iron cores is necessary; but he may for want of full electrical knowledge apply both the insulation and the lamination in an entirely erroneous manner, and produce a dynamo that will break down directly it is put to any severe test.

Amongst the complaints to which armatures are subject are the burning-out of coils, the burning of the binding wire, and the breaking off of the conductors near the ends where they go to join the respective parts of the collector. The burning-out of coils is sometimes due to short-circuiting at the collector between two adjacent sections; but often it arises from short circuiting in the armature itself. In armatures so constructed that the windings of one section lie partly over the top of those of another section this evil is more likely to occur than in those that are not so constructed. Short-circuit between an imperfectly insulated wire and the iron core beneath it is a frequent source of trouble, and this again arises either from bad mechanical work allowing the iron laminæ to become loose, or from the use of unreliable insulating materials. Sometimes armatures are destroyed by charring of the insulation, not in consequence of the overheating of any of the wires, but from the overheating of the iron cores. In such cases either the iron is not properly laminated or else the insulating material between the iron laminæ has failed to insulate. The burning of binding wire clearly arises from want of compliance with the necessary and sufficient electrical conditions. The fracture of the armature conductors near the ends where they turn over to the collector—a most annoying fault when it occurs—appears to be partly mechanical and partly electrical. These conductors are at this point not supported laterally; any engineer would imagine that they were strong enough to stand any longitudinal or centrifugal force to which they might be subjected. Yet they have to withstand severe lateral forces, arising from the fact that they carry strong currents and are situated in a fairly powerful part of the magnetic field, which here extends beyond the edge of the polar surfaces. Hence they are each racked by a lateral force that comes upon them

* Paper read before the Finsbury Technical College Old Students' Association, November 29th, 1887.

Digitized by Google

twice in every revolution; and which, moreover, must strain them severely whenever the current is suddenly cut off or turned on. The collector or commutator and its brushes are a fruitful cause of trouble. Brush-holders are rarely as substantial as they should be. The conditions of good mechanical work and good electric work are here somewhat antagonistic; but the mechanical work must be good, otherwise the best observed electrical arrangements will fail. The brushes must not slip or jump with the vibrations of the machinery. If they press too heavily, the surface of the collector will be torn into ruts; if too lightly, the edges of the separate sections of the collector will be bitten and rounded by sparks. The curious disease known as the occurrence of "flats" in the collector has been a source of puzzle and annoyance to many. In many cases the occurrence of a "flat" may be definitely traced to a more or less developed fault in some one section of the armature coil. A broken armature coil, the ends of which still touch against one another within their insulating sheath, may go unsuspected; but it may have the effect—by its increased resistance—in causing an increase of spark at the brush just as it passes through the position of commutation. Hence the corresponding bar of the collector will at every half-revolution be bitten into by a spark a little more than any other bar is bitten into, and so become flattened as compared with the proper peripheral curvature of its fellows. "Flats" do not, however, always arise from this cause. It has been observed that a "flat" may break out on one bar of the collector; and on turning down the surface of the collector so as to remove it, a "flat" breaks out on another bar of the collector. A "flat" may arise from a flaw in the metal of the bar, which passing under the brush, gives rise to a spark that bites away the metal a little further to right and left, and so spreads along the bar until the whole surface of it is more or less bitten away. A little more pressure on the brush, and a better mechanical holding of the brush, are remedies not to be despised. The collector is the one part of the machine most likely to give trouble; it is rarely made large enough; years of experience have not yet given any decisive answer to the question, what materials it should be made of? Whilst English makers are almost agreed upon using either hard drawn copper or else some kind of hard bronze with mica insulation between the bars, Messrs. Siemens and Halske have this year abandoned these for iron bars with air gaps between. Before mica was in general use asbestos was not unfrequently employed, and with curious results. At one time the writer was working with a small Siemens shunt dynamo, giving on open circuit about 80 volts. One day it gave only a little over 70, though the speed was normal. The next day it was under 70, the next it refused to excite itself. The circuits were tested out, as a fault in the shunt, increasing its resistance, was suspected; but there was nothing found wrong. When separately excited from accumulators, it, however, gave only 15 volts on open circuit. In vain the brushes were replaced and the brush-holders cleaned. There was plenty of magnetism, for the armature got hot; yet no sparks, or next to none, at the brushes, even when short-circuited. Suspecting that some of the armature coils were short-circuited, an attempt was made to test the resistances between bar and bar of the collector, but without any very decisive results, owing probably to the roughness of the test. However, there were noticed some slight inequalities, which gave a clue to the cause of trouble. On examination it was found that nearly every one of the collector bars was more or less short-circuited to its neighbour by a charred mass of carbonised oil imbibed into the asbestos which formed the insulation. It was dug out with a penknife and replaced by another material, when the dynamo was restored to its proper activity. This vice has been of not unfrequent occurrence. Only a few weeks after the occurrence named the writer received an urgent call to go to a town in a distant part of England, where a dynamo refused to work. Being unable to leave home that day particular inquiries were addressed by telegraph, and yielded the information that it was a Siemens shunt machine, that all the circuits tested right, but still the machine would not excite itself. Instructions were despatched to dig out the insulation between the collector bars, and the remedy proved effectual. Obviously, in such cases, oil ought not to be used on the collector, but only asbestos dust or French chalk. The writer has subsequently learned that a very similar trouble sometimes arises in certain machines that have collectors so constructed that there is a cylindrical cavity beneath the collector bars into which oil from the lubricators at the bearings may drain, and in which a charred mass ultimately forms short circuiting the entire collector. Another cause of trouble is the small metallic dust which flies from the collector when the brushes press so heavily as to produce ruts, entailing consequences partly mechanical and partly electrical that may end in a breakdown.

Amongst other faults of armatures that give trouble there is a purely mechanical one, arising from want of knowledge on the part of the electrical designer, namely, that of not being properly balanced. Every engineer worthy the name knows that a thing so balanced as to stand in any position is not necessarily balanced for running; that a four-pound weight at three inches from the axis of rotation, though balanced statically by a one-pound weight at twelve inches from the axis, is not balanced by it dynamically, for the moments of inertia about this axis are not equal. On the contrary, a four-pound weight at five inches is balanced dynamically by a one-pound weight at ten inches from the axis. A machine that violates dynamical principles can never be satisfactory. Short bearings where long ones would be appropriate; a high-speed machine where a low-speed machine is the only suitable sort (for example, on ship-board); inside bearings where outside ones ought to be used, and *vice versâ*—all these things have been and may still be answerable for breakdowns. So much the more reason is there for the electrical engineer to be engineer first and electrician afterwards. Not that electrical knowledge is to be despised. The writer once heard an experienced engineer who had been put in charge of a dynamo which was lighting some arc lamps, and doing its work badly, declare that the trouble arose, not from an insufficient supply of current—he did not dispute the quantity of the current—but from the current being of a rather poor quality. There were, in point of fact, too many lamps in the circuit. Again, it is a fact furnishing food for reflection that in those electroplating shops in London where dynamos are used the practical men in charge almost invariably hold the firm opinion that they are not getting the proper current unless they can see sparks at the commutator. They therefore so adjust the brushes that they get a good blaze. Sparking at the commutator or collector is a symptom of disease in a dynamo, just as truly as an outbreak of pustules is a symptom of disease in the human subject.

In the field-magnets vices of construction are more frequent than acquired defects. Field-magnet coils are sometimes wound on frames that are loose, or the coils are badly insulated. When the frames are loose the resulting vibration not unfrequently causes the ends of the wires to snap off short. If there is a single short circuit between coils and ironwork in the field-magnet, then a single short-circuit at any other point—armature coils, collector bars, brushes, brush-holders, or terminals—may work dire disaster. A little Brush machine lent to the Finsbury Technical College by the Anglo-American Brush Corporation had its commutator segments completely ruined in a few minutes by a curious double fault of this kind, which defied detection for several days. There were two short-circuits, neither of which in itself would have have done any harm whatever; but the iron support that held the rocker for one pair of brushes was so fixed by screws as to make a cross connection that short-circuited two pairs out of the four pairs of coils on the armature. A short-circuit between coil and iron core of the field-magnet is more likely to arise in shunt machines or compound machines than in series-wound ones, owing to the much higher electromotive force of the self-induced extra current if the shunt-circuit is from any cause opened. Alternate current dynamos are liable to develop different kinds of faults from those to which direct-current machines are liable. They sometimes exhibit a curious pulsation of a determined slow period in their currents. The cause for this is probably purely mechanical. Again, machines for constant current are liable to disorders of a different nature from those of machines intended for constant potential work. The latter are

Digitized by Google

more liable to overheat; the former are more troublesome in respect of sparking, because of the very great variations in the position of the neutral point.

Very little attention seems to have been paid to the question of the goodness or badness of insulating materials for resisting being broken down under working conditions entailed by damp, dust, and oil. Under such conditions it does not in the least follow that the material showing the highest insulation tests is the best. Very few dynamos will show, even when new, an insulation-resistance between iron work and copper work amounting to anything like one megohm. Yet a dynamo that showed only ten thousand ohms of insulation-resistance and mechanically resisted being broken down, would be preferable to one the insulation-resistance of which was a hundred megohms, if that high resistance were secured by employing brittle materials or materials that were destroyed by the presence of oil. Whether mica is in all cases preferable to asbestos, Willesden paper to vulcanised fibre, or shellac varnish to a solution of india rubber, or what other insulating materials should be prescribed in preference, can only be ascertained by a careful study of the failures that have from time to time arisen when one or other was employed.

Only by the study of the malady as it arises can the proper treatment be discovered to prevent its recurrence. In short, by the proper study of dynamo-pathology, we may arrive at a fuller knowledge of dynamo-therapeutics.

DISCUSSION.

Mr. JONES, referring to pulsation on alternate current circuits, said that in one case in London, where two such machines were used, he had traced a very troublesome pulsation to the collector, which had worn oval. The fault was removed by turning up the collector.

Mr. ESSON was of opinion that engineering faults were generally the cause of breakdowns. Speaking of the relative merits of armatures in which the wire was supported by metal projections, and of those where the wire was held on merely by friction, he stated that he had never seen a fault from the wires being attached in the latter manner. The breaking of wires leading to the commutator was more common in motors than in generators. He thought it was due to the spindles bending. For commutators he recommended gunmetal, where great pressure was required to prevent vibration, as in motors on tramcars; in other cases hard-drawn copper, lubricated with vaseline. He thought that unequal sparking of brushes was due to the field being made unequal by the presence of masses of iron about one of the poles.

Mr. MORDEY thought the fault of the breaking of wires near the commutator was an obscure one; it had never been quite satisfactorily explained. He recalled a paper published some five years ago by Hefner von Alteneck, in which the fault was discussed, but left unexplained. Prof. Thompson's suggestion was a good one, but he thought that the first effect of the movement of the wires in the fringe of the field should be to give them all an inclination in one direction. This did not occur, and he thought, therefore, that Prof. Thompson's suggested explanation was not quite satisfactory; neither did Mr. Esson's quite fit in with many cases where the fault had been observed—that was in the steady running of dynamos. The fault had never occurred in Brush or Victoria dynamos. The pulsation in alternating current dynamos was often noticeable. In one large installation in London, where the dynamos were driven direct, the pulsation was very marked, and appeared to be too quick to correspond with the speed of the engine, and too slow to be due to the actual alternations. Referring to commutators he said that various lubricants had been recommended. Sir Wm. Thomson was credited with advancing the claims of treacle for this purpose. He thought that the lubricator was the least important matter in successful collection; nor was it very important how the brushes should be made provided they were not too thick. Carbon had been recommended for brushes, but he thought carbon should be reserved for the arc lamps. The unequal sparking and heating of brushes had often been noticed, and he was inclined to attribute it to an effect similar to that which occurred in arcs, where one electrode got hotter and burnt away faster than the other. He asked others to try, by reversing the polarity of the magnets, whether they could confirm or disprove him. The difficulty was that sparking in modern dynamos was usually very slight, and convincing results were difficult to obtain. The effect of any inequality of the distribution of the fields would be removed by reversing the polarity of the magnets. After describing some simple methods for localising faults in low-resistance armatures—matters in which ordinary bridge and other measurements were of no use—he referred to the question of insulating materials, on which Prof. S. P. Thompson had made some observations. Vulcanised fibre was a very unsatisfactory insulator. The material itself was probably good, but he thought the manufacture could not be carefully conducted, as the substance frequently broke down in a way which seemed to indicate that metal filings or other foreign substances were rolled into the sheets. While acknowledging that dynamos were liable to suffer from many diseases, he thought they should not be too harshly blamed, and mentioned a case where of two similar machines one was always found to require a higher speed of the engine and apparently to absorb more power than the other. He traced the loss to a friction clutch which had been allowed to become covered with oil, and was slipping and absorbing about 18 horse-power.

Mr. D. PEARCE said that he had found the insulation of some Siemens dynamos was very low, the paint used having quite soddened the cotton with oil. He mentioned a case of unequal heating of brushes, where the positive brush always wore several times as fast as the negative. The fields had been reversed, but without effect.

Mr. SUMPNER said that in taking the curve of a Ferranti dynamo he had found that there was an occasional departure from the sine curve, caused by an inequality of the winding.

To this Mr. MORDEY objected that as all the armature coils were in series, all the curves must be alike, any inequality affecting the curve similarly at every alternation.

Prof. THOMPSON remarked that an inequality in the armature winding and another in the field would account for the discrepancy, which would then occur once in every revolution.

After some remarks from Mr. HOWARD SWAN, Mr. DICKSON, and other members, and from Mr. PETTIGREW, who occupied the chair,

Prof. THOMPSON replied. He said that the thickness of brushes should be such that the current should have time to die out of the coil under the brush, to start again, and to come up to the strength of the main current before the coil was again thrown into the circuit. He did not quite give up his idea that the breaking of wires was due to the magnetic field. The sudden putting on of the current in motors would account for the increased occurrence of the fault in them. In motors the brushes might be wider than in generators. Alteneck had told him that the fault had been entirely got rid of by connecting the segments to coils 90 degrees removed from them. He thought, and had previously pointed out, that unequal fields were often a cause of sparking, and that on this account double magnets had an advantage.

A cordial vote of thanks to Prof. Thompson for his interesting and instructive paper terminated the proceedings.

ON THE ACTION OF AN ELECTRIC CURRENT IN HASTENING THE FORMATION OF LAGGING COMPOUNDS.*

BY DR. J. H. GLADSTONE, F.R.S.

When two salts in solution, MR and M'R', are mixed together they partially decompose one another, the proportions of the four resulting salts MR, MR', M'R, M'R', depending upon their relative masses and relative affinities. When one of these salts is insoluble it separates as an amorphous or crystalline precipitate, and the redistribution goes on until the largest possible quantity of it is formed and precipitated. This reciprocal decomposition generally takes place very rapidly, but in some cases it proceeds slowly enough to be watched and measured. While investigating this subject a good many years ago, I made some experiments on the physical forces that accelerate or retard this action, and among them I tried the influence of a voltaic current passing through the mixture. I used a small Grove battery with narrow platinum poles.

1. The first experiment was made with a mixture of tartaric acid and nitrate of potassium. The strength of the tartaric acid was 4·5 grammes, and of the nitrate of potassium 1·02 gramme to 1,000 grain measures (*i.e.*, 64·8 cubic centimetres) of water; and the proportions used were three equivalents of the acid to one of the salt. In a comparative experiment four minutes elapsed before crystals began to appear on making the current, the pole from which oxygen gas was being slowly evolved became immediately coated with potassic bitartrate, and crystals formed throughout the liquid between the poles.

2. A similar result was obtained with potassic oxalate and magnesic sulphate.

3. A mixture of single equivalents of magnesic sulphate and oxalate of ammonium was divided into two portions. Through the one a weak current was passed, and after a few minutes a cloudiness appeared, extending in lines from the one pole to the other, and not below the poles. As yet there was no cloudiness whatever in the comparative experiment.

4. A similar result was obtained with a mixture of calcic sulphate and strontium nitrate, but the lines of cloud extending from the oxygen towards the hydrogen pole were still more remarkable. The comparative mixture was quite clear.

* Read at the British Association, Manchester, as part of the Report of the Electrolysis Committee.

Digitized by Google

5. A mixture of citrate of iron and meconic acid goes on increasing in redness for some time, but in this case all the compounds are soluble in water. No acceleration seemed to result from the passage of the galvanic current.

6. A mixture of citrate of iron and ferrocyanide of potassium shows a gradual formation of the blue ferrocyanide. This was hastened by the galvanic current ; but there is this objection to the experiment, that the ferrocyanide itself was somewhat decomposed.

Last autumn a neighbour of mine, Mr. J. Enright, wrote to me to the following purpose :—"Thinking one day some few months ago over the decompositions and recompositions which we figure to ourselves as going on in an electrolytic salt, it occurred to me that we might get some confirmation, or the reverse, of them from passing a current through a mixture of dilute sulphuric acid and a salt of strontium. It is well known that a precipitate does not come down for some time, and that such time is shortened by heating." He then describes an experiment that is practically the same as my own, for which he used five Bunsen cells, and a similar experiment with a potassium salt and tartaric acid, and in both instances he obtained an acceleration, as I did. He adds, however, a somewhat different experiment. Cyanide of potassium was added to a solution of a nickel salt, and the first precipitate was redissolved in excess. Then hypochlorite of sodium was added. On boiling such a mixture, or allowing it to stand for some time, a black precipitate appears; but the moment the electrodes were inserted in a portion of the mixture, although cold, a black cloud was formed.

More recently Mr. Enright, at my suggestion, tried the effect of varying the strength of current. Using a mixture of strontium chloride and sulphuric acid, which would give a turbidity in about seven minutes without the current, he found that when exposed to the influence of seven cells the turbidity appeared in four minutes, of six cells about the same, of five or four cells in four minutes and a-half, of three cells in six minutes, while two cells did not produce any acceleration that could be distinctly recognised.

These experiments seem in accordance with what might be expected if the electrolytic action takes place through the interchange of the radicles of the dissolved salts.

THE DIFFERENT VARIETIES OF THUNDERSTORMS, AND A SCHEME FOR THEIR SYSTEMATIC OBSERVATION *

BY THE HON. R. ABERCROMBY.

The author shows that there are at least three distinct types of thunderstorm in Great Britain. The first, or squall thunderstorms, are simply squalls associated with thunder and lightning, which fly nearly with the surface of the wind. These form on the sides of primary cyclones. The second, or secondary thunderstorms, are associated with secondary cyclones. These move against the surface of the wind, and are very rarely accompanied by squalls. Very little is known of the nature of these squalls, though they are the commonest type of thunder in Great Britain. The third, or line thunderstorms, are apparently of a totally different nature. They take the form of long narrow bands of rain and thunder, perhaps 100 miles long and only 5 or 10 broad. They cross the country rapidly nearly broadside on. These are usually preceded by a very violent squall. The squall which capsized the "Eurydice" was of this type. The air in thunderstorms seems to circulate round a long horizontal axis which would lie in the direction of the thunderstorm instead of round a short and nearly vertical axis, as in cyclones. The outline is given of a proposed scheme for the systematic observation of thunderstorms in England, by which it is hoped that the mechanical nature of the circulation of the air in every kind of thunderstorm may be discovered. It is also shown that if that particular kind of thunderstorm which is not associated with any distortion of isobaric lines can be worked out, a kind of rain could then be successfully forecast which is now very rarely announced. Forecasters now have to depend almost exclusively on synoptic charts of isobaric lines. To this extent they fail ; but it is hoped that observations in the form and motion of clouds may be found to indicate the approach of rain when the barometer shows nothing.

* Abstract of a Paper read before the British Association Meeting at Manchester, September, 1887.

REPORT OF THE BRITISH ASSOCIATION COMMITTEE ON ELECTRICAL STANDARDS.

The committee was appointed for the purpose of constructing and issuing practical standards for use in electrical measurements. The committee report that the work of testing resistance coils has been continued at the Cavendish Laboratory, and a table of the values found for ten various coils is given.

Legal Ohms.

No. of Coil.	Resistance in legal ohms.	Temperature.
Elliott 183, C.C.L. 173	·99938	16°3
Elliott 184, C.C.L. 174	·99924	16°3
L Clark and Muirhead 251, C C.L. 175.	10·0040	17°
Elliott 117, C.C.L. 63	·99976	15°9
Elliott 185, C.C.L. 176	·99962	15°8
Elliott 186, C.C.L. 177	·99959	15°8

B.A. Units.

No. of Coil.	Resistance in B.A.U.	Temperature.
Elliott 41, C.C.L. 55	1·00286	16°2
Elliott 56, C.C.L. 56	1·00039	16°
University Coll. coil, C.C.L. 63	·99983	16°2
Taylor's coil, C.C.L. 68	·99985	18°25
Taylor's coil, C.C.L. 69	10·00209	18°1
Price coil, C.C.L. 66	1·00289	19°2
Price coil, C.C.L. 67	1001·39	19°4
Warden 292, C.C.L. 70	9·99416	16°5

Of these, the coils Elliott, Nos. 41, 56 and 117, have been tested before, but owing to the green colouration mentioned in the last report, showing itself in the paraffin, the paraffin was removed and the coils refilled with ozokerit, which can be obtained more nearly free from traces of acid. This change in all cases produced an appreciable increase in resistance, amounting in the case of Elliott 41 to about ·0025. The coils C.C.L. 63, 68 and 69, are three of the original B.A. units. C.C.L. 70 is a coil sent over from the Johns-Hopkins University for the purpose of connecting their value of the B.A. unit with that found at the Cavendish Laboratory. Shortly after the Birmingham meeting of the Association the secretary received a letter from the Board of Trade, enclosing a copy of the general bases of a convention proposed by the French Government for the consideration of the Powers with the object of carrying out the resolution of the Paris Conference with regard to electrical standards. The convention stipulates that a legal character is to be given to (1) the legal ohm, (2) the ampere, (3) the volt, (4) the coulomb, (5) the microfarad. These questions had been considered by the committee at the Birmingham meeting, and the following series of resolutions, which the secretary was instructed to forward to the British Government, had been agreed to on the motion of Sir W. Thomson, seconded by Prof. W. G. Adams : (1) To adopt for a term of ten years the legal ohm of the Paris Congress as a legalised standard sufficiently near to the absolute ohm for commercial purposes ; (2) that at the end of the ten years period the legal ohm should be defined to a closer approximation to the absolute ohm ; (3) that the resolutions of the Paris Congress with respect to the ampere, the volt, the coulomb, and the farad be adopted ; (4) that the resistance standards belonging to the Committee of the British Association on Electrical Standards now deposited at the Cavendish Laboratory at Cambridge be accepted as the English legal standards, conformable to the adopted definition of the Paris Congress. In reply, therefore, to the letter of the Board of Trade, the secretary sent a copy of the above resolutions with a statement of some reasons which had led to their adoption. During the year the original stan-

Digitized by Google

dards of the Association have again been compared by the secretary. An account of this comparison and of the very complete one made in the years 1879-81 by Dr. Fleming, the details of which have not been published previously, is given in appendix. The general result of the comparison is to show that there is no evidence that any of the original coils have changed in value since the year 1876, when they were compared by Prof. Chrystal and Mr. Samuda.

The results of this comparison showed that with the exception of the coil G (No. 43 in Mr. Hockin's report) no change had taken place in the relative value of the coils since Mr. Hockin's comparison in 1867. The coil G has certainly not changed since 1876, and it seems probable, for reasons given in the appendix, that the difference between its values of 1867 and 1876 was apparaent, and not real. Thus, with the possible exception of this coil G of platinum silver wire, the relative values of the seven coils remain as they were twenty years ago.

At the last meeting of the committee it was resolved, on the motion of Mr. W. H. Preece, seconded by Sir William Thomson, to recommend the adoption of the watt as the unit of power. The watt is defined to be the work done per second by the ampere passing between two points between which the difference of potential is one volt. The committee were also of opinion that it is highly desirable to proceed with the construction of an air condenser as a standard of capacity, and for this purpose they desired to be reappointed with the addition of the name of Mr. Thomas Gray, and a grant of £100.

THE "WOOD" AMMETER AND VOLTMETER.

An ammeter and voltmeter based upon the principle of the repulsion of similar poles is not an entirely novel device. It has been employed, for instance, for several years by Mr. Arthur Wright; but considering the advantages which are obtained it is remarkable that more extensive use has not been made of the idea. These advantages are chiefly the absence of permanent magnets, and the comparative ease with which the deflections of the pointer can be made strictly proportionate throughout the scale. This is done by an empirical adjustment of the shape and position of the pole-pieces, between which the repulsion takes place. Of course the instruments labour under the inevitable defect of all soft iron apparatus that the past magnetic history of the iron affects the subsequent readings.

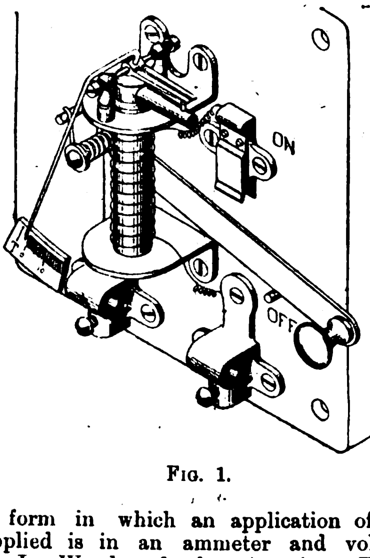


Fig. 1.

The latest form in which an application of this principle has been applied is in an ammeter and voltmeter designed by Mr. J. J. Wood, of the American Electrical Manufacturing Company. The details of these instruments seems to have been very carefully worked out. The diagram (Fig. 1) shows one construction of a voltmeter, Fig. 2 showing the principal part in detail. As will be seen it consists of a core of soft iron, around which a coil of high resistance is wound. This core has a projection, N N, which is given a north polarity by the current, as shown. Pivoted above the core, and in line with the projecting arm, is a soft iron armature carrying a pointer which passes over a scale. Now, it will be seen, according to the well-known law, that the part of the armature immediately over the core of the electro-magnet will have a south polarity, S', induced in it, and correspondingly a north polarity, N', at its outer end. The consequence is that upon the passage of a current through the coil the inner ends N S' will tend to attract each ether, but are kept stationary by the pivoted armature. But the outer ends N and N', being of the same polarity and one of them being free to move, they repel each other, and the end N' is repelled to a distance corresponding to the strength of current in the coils, *i.e.*, the potential at its terminals. The pointer being rigidly fixed to the swinging armature, it indicates the deflection on the scale.

With pure, soft iron and working below the limit of saturation of the iron core, the magnetic capacity of the latter not only remains constant, but its strength ought to be almost in exact proportion to the inducing current. And it is a remarkable peculiarity of the instrument that the deflections on the scale are practically equidistant over the entire range. When the pointer is at the farthest end of the scale the armature S' N' stands almost vertical.

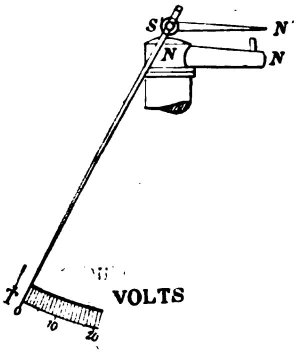

Fig. 2.

It will be noticed that the balancing force employed in opposition to the magnetic repulsion is gravity, no springs being employed.

When the instrument is set up, the pointer is carried over towards the left until the outer end of the armature S' N' strikes the projecting arm of the electro-magnet, and then while these two are in contact the pointer is bent until it comes opposite the mark T (test). The armature is then released, and, swinging upward a short distance out of contact with the projecting arm, it brings the pointer opposite the zero mark on the scale. This method of testing is provided so that if, during transportation or otherwise, the pointer should become bent, it can be readily corrected so as to give accurate readings.

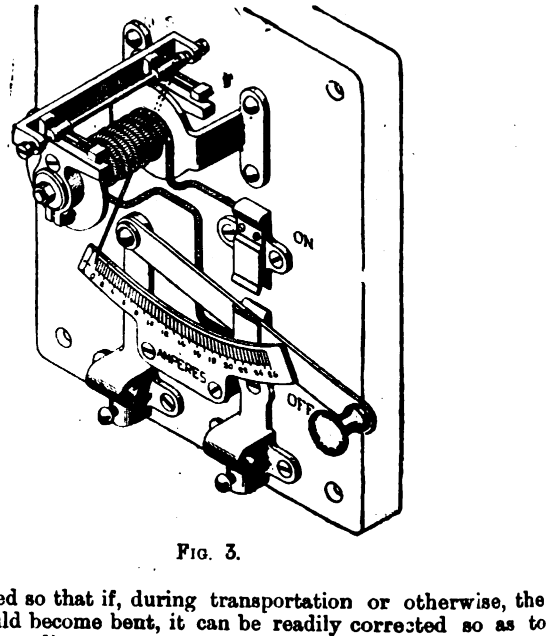

Fig. 3.

Another form of instrument embodying the same principle, and shown as an ammeter, is illustrated in Fig. 3. Here, it will be noticed, both poles of the electro-magnet are brought into play, and act upon two armatures fixed to the same spindle. The action is, of course, the same as that of the instrument just described. In this form, it may also be noticed, the core of the electro-magnet is built up of Norway iron wire, thoroughly annealed, the ends carrying soft iron pole-pieces, which act upon the armatures.

These instruments have been in use for some time in America, and are, as we are informed, doing excellent duty.

CORRESPONDENCE.

THE FIRE OFFICE RULES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 14th October it is announced that the question of fire office regulations as to electric lighting has been settled by the adoption of the Phœnix rules; but as I think it will be found upon inquiry that the committee of fire offices and the Society of Electricians, to whom the subject was referred, have not yet come to any decision thereon, perhaps you can throw some further light upon the matter.

In the various discussions which have taken place upon the precautions necessary against fire in electric light installations, it is rather disappointing to find that no credit is given to the New York board of fire underwriters for their rules of January, 1882, October, 1884, and February, 1885, which have been of such assistance in framing the present rules upon the subject. The earliest English rules are dated February, 1882, and are almost literally a copy of part of the American rules.

It is much to be hoped that when the new rules do appear, they will be as simple and concise as possible, and that there will be no variations allowable at the will of the fire office inspectors, as that practically makes the rules so much waste paper.—Yours, &c., WM. RAWLINS.

London, 29th November, 1887.

[We print this letter with some reluctance, as we are strongly of opinion that the reopening of the question is very much to be deprecated, and is only calculated to do mischief. Our own columns have shown that the feeling of the leading firms is overwhelmingly in favour of the existing rules. It does not seem to be sufficiently realised in some quarters that any unnecessary tampering with questions of fire insurance can only be injurious to the trade.—ED. *E.*]

THE "COWLES" PROCESS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your issue of the 4th ult. a remarkable article on the Cowles aluminium process. As an old experimenter in these processes I might perhaps show that the Cowles Brothers are somewhat sanguine as to the finality of their so-called process. But for the time being I only wish of you, in favour of truth, to allow me to say that the process in question is patented by me under the date of 22nd November, 1883, as an improvement on Benzer's patent of 1858. It may be that one of Cowles' agents having bought from me a patent of 1882 they believe they own my process; but this is not the case, and I am since last year operating quietly in England preparatory to placing my process before the public.—Yours, &c., C. A. FAURE.

206, East Ninth-street, New York, 14th November, 1887.

WELDING BY ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your impression for last week I notice some extracts from Prof. Rühlmann's report (a copy of which I have with me) on Benardos' method of welding metals by means of electricity. I am sorry I cannot agree with him in all he says about the quality of work produced by the inventor.

I went this summer to St. Petersburg for the purpose of examining and reporting on the invention in question, and spent some little time in carefully noting down what I saw of the process. The specimens of welding M. Benardos showed me as having been made by his process certainly seemed to me to be all that could be desired as far as external appearances went, but pieces of metal which were welded together in my sight, and which afterwards I had cut into sections, were in a very unsatisfactory state at the join. In specimens which I brought home with me the metal was brittle, and burnt where it had been under the action of the arc.

Hearing that the invention had been taken up in Paris, I went there to see what was being done, and although I could not have my own pieces of metal operated upon owing to a breakdown of the machinery, I brought away some specimens, which were, however, no better in quality than those I brought from St. Petersburg. In my opinion the use of the arc is to be condemned, as, I think, from what I have seen, it is impossible to escape burning the metals (in the cases of steel and iron) in a more or less degree.—Yours, &c., E. J. RYVES.

Nov. 28th, 1887.

THE TRAINING OF ELECTRICAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your valuable article (November 25th) on the "Training of Electrical Engineers" will probably lead to a correspondence in your columns from which much good may result. As a contribution thereto, may I trouble you with the following remarks, the preface to which must be a word of thanks for your kindly recognition of the efforts of the professors and teachers of the colleges and similar training schools.

Speaking now as one who has for many years been concerned with the teaching of mechanics and physics, but speaking also as one who for 14 years was the manufacturing partner in a business employing 300 workpeople, I desire to bear emphatic testimony to the fact that you have struck at the root of the whole matter when you say, "For a purely scientific vocation the college training is, of course, an indispensable beginning; but what we are dealing with is a matter more nearly related to pure business than to pure science."

As the head of a technical school which is endeavouring to meet the needs of the profession, may I briefly point out the nature of our chief difficulties, since they, in great measure, confirm your own views? As regards the theoretical training, the most important is the almost utter impossibility of making the average student and his friends see the necessity of learning the elements of practical and theoretical mechanics and *a fortiori* mathematics as essential preliminaries to his training. During the past year the course of instruction here has been considerably extended in this direction, an alteration which has met with much internal opposition, although the fact has been repeatedly pointed out that the managers of the school attached sufficient importance to it to spend £600 thereon to enable the practical part to be thoroughly taught. The conditions attached to the granting of our Vellum Certificate of "passing in mechanical and steam engineering" are regarded as severe and unnecessary, and are a greater cause of failure and delay than any other.

It is, however, in the case of the advanced class, when for half the day I endeavour to make the conditions under which the students work as nearly as possible like those which would obtain in a manufactory, that the greatest practical difficulties arise. The instructor in charge (who here corresponds to the shop foreman, the students representing the workmen) gives out certain work, or allots certain duties, to each student. In cases that occur far too frequently, however, these duties are neglected as soon as the foreman's back is turned, or the student fails to do the allotted work at the appointed time. As a practical instance of this, we frequently have the whole morning's work delayed, if not spoiled, because the students in charge of the engine and boiler do not come early enough to get up steam by ten o'clock. A manufacturer has his remedy for this in the immediate discharge of such workmen, but a manufacturer whose pupils pay him a premium cannot discharge them. It is obvious that this state of things arises from the complete failure of students to realise their responsibilities to themselves, their friends, their instructors, and their future employers, as well as from their want of real interest in their work, and of perseverance in the face of difficulties.

These, Sir, are some of the difficulties which beset those who endeavour to train young electrical engineers. That they have not been altogether unsuccessfully met will be admitted, I think, by many who have had *certificated* students from here. May I be permitted to cite one instance? A well-known firm took into their employ several months ago (after long repeated requests on my part) a student who was "the best of his year" here. After he had been with his employers a very few weeks, they *voluntarily* wrote to me to say that "We did not think he could possibly have learnt as much as he has

Digitized by Google

at your school," and added that they had no doubt of putting him on their permanent staff. I know that he has received a salary for the whole time that he has been in their employ, and I also know that when he came to me he had received nothing more than an ordinary grammar school education, but that he had a "turn" for mechanics.

In conclusion, may I be permitted to add that I am at all times glad to receive visits or letters from manufacturers on the subject of education for electrical engineers, and wish that I had more such communications from them ?—Yours, &c.,

WM. LANT CARPENTER,
Manager of the School of Electrical Engineering.
12, Princes-street, Hanover-square, London,
November 29th, 1887.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am very pleased to see that you have taken this very important matter up in your leader columns. I think it would be difficult to overrate the gravity of the question of the training of those upon whom depends the proper carrying out of electrical work. I also agree with you that a college training, or a technical school training, is of very little use for practical work. Young fellows spend a year or two years at a technical school, and having carried all the honours that are open to them, imagine that they are fully qualified to take appointments as salaried engineers; whereas they have only been preparing to learn the real work they will have to perform. In their year or two or three of study, as the case may be, they have only played at practice, and they have probably only acquired as much real knowledge of electrical engineering as they would have acquired in a workshop in a few months.

There is only one method of acquiring practical experience, and that is in practice; and without practical experience an engineer is worse than useless—he is a minus quantity so far as the work is concerned.

On the other hand, I do not believe in boys being placed in the workshop too young. Eighteen years of age is quite early enough, and the three years between fifteen and eighteen can be advantageously employed in acquiring a knowledge of mathematics and modern languages, of which they may never have another opportunity, as in electrical engineering it requires a man's whole time and abilities, once he becomes a breadwinner, to keep pace with the times.

It is wrong also to expose a boy much under eighteen to the influences of the workshop. At eighteen he has more ballast on board, and can stand it better. My own experience in training young fellows has been as follows:—

In the most successful cases they have come to us at about eighteen, having received a good education both physically and mentally. In most cases they have known absolutely nothing of electrical work before coming to us. They have been at once placed in the workshop, and taught to see and to assist with their own hands in everything that is going on. For instance, they will themselves make batteries and bells, wind armatures and field-magnets, and assist in construction work generally. When installation work is on they go out and assist in fixing, starting, or repairing apparatus where necessary; and they are encouraged to ask the reason for everything they see done. I find that it takes months for a young fellow, coming fresh to the work, to settle down to practical workshop details; it is so strange to him, so different from school or college life. During that time, however, he is, in the majority of cases, acquiring the very knowledge the schools are aiming at imparting in their two or three years' course; but with this difference, that he has it more firmly impressed on his mind, from the fact that he sees the whole actual process, and knows the reason for each step of it. After six months the wonderful fascination which the study and practice of electricity exercises over most minds asserts itself, and he is ready to go anywhere and do anything. In twelve months he has generally begun to be useful to go after faults, take details for estimates, perform experiments, take tests, &c. In two years he is capable of efficiently taking charge of an installation, supported, of course, from behind; but he is made to thrash out his own difficulties, guided where necessary for the sake of the business. And in three years, so far, we have always been glad to take him on at a salary. As far as I can make out, if we had taken on any of the students from the technical schools to do the work which our own pupils do we should have been obliged to train them from the very beginning.

I should say that any body—such as the proposed Association of Electrical Engineers—who will grant some form of certificate of qualification, after assuring themselves that the applicant fulfilled the necessary requirements, will confer a boon upon every one concerned. There have been too many cases of men gravitating into electrical engineering, not because they had a genuine liking for it and were ready to go through the necessary training to become qualified, but because they thought it was easy and well paid; and it is to these men and to the theoretical men who come principally from the schools that most of the failures are due.

Any association or any system that will check this will do splendid service to the cause we all have at heart.—Yours, &c.,

SYDNEY F. WALKER.

195, Severn-road, Cardiff, November 29, 1887.

TYPE-WRITING TELEGRAPHS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last week's issue an electrical type writer of American invention, which can also be used as a telegraph, is mentioned.

Will you permit me to point out that such an apparatus has been in existence in this country and used by the Exchange Telegraph Company for some years past, my first patent being dated November, 1880.

I enclose a specimen of the work done by this apparatus, which may be effected at any distance from the operator and upon any width of paper. The printing is not inferior to that of most ordinary type writers, and the instrument is smaller than most of them. No clockwork is employed, and the message is received automatically.—Yours, &c.,

F. HIGGINS.

The Exchange Telegraph Co., 17 & 18, Cornhill, London,
28th Nov., 1887.

[The specimen enclosed by our correspondent is printed on ordinary paper *(not on tape)* and would be taken for the work of any ordinary mechanical type writer.—ED. *E.*]

TRADE DISCOUNTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Sydney F. Walker in his criticism on Mr. Money-Kent's "Note on Trade Discounts" first takes upon himself, on behalf of practical men, to censure the use of mathematical calculation in business matters—which is a rather bold thing to do and savouring of "Podsnappery"—and then, having settled that point, he has the kindness to extract for the "benefit of your readers" the arithmetical statement made by Mr. Money-Kent, and to advance the same as a rule of his own to which his former strictures are inapplicable.

If the calm audacity with which the algebraic result is *borrowed* for the purpose of proving the futility of the algebraic operation were not so laughable, Mr. Money-Kent would justly feel that insult was here added to injury; as it is, however, I should imagine there can be no sting in Mr. Walker's innocent remarks.

I may say that my experience has been identical with Mr. Money-Kent's as to the fumbling methods usually adopted in the office for solving such questions as he deals with, and two or three years ago I had occasion to resolve the formula $\lambda = \frac{100\mu}{100-\mu}$ which he gives, for my own use.

I think that, perhaps, a less elegant working would have been equally efficacious, and I remember that I only used the most rudimentary algebra for my purposes when dealing with the same point.—Yours, &c.,

GUY C. FRICKER.

PRIMARY BATTERIES: AN ENCOURAGING EXPERIENCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is with great diffidence that I venture to write to you again on the subject of primary batteries, and in doing so can only, for the benefit of the public, give my practical experience of them. Mr. Preece, who is a very great authority on electrical matters, says he is assured that "to utilise batteries for the lighting of mansions and smaller houses must end in disastrous failure." Doubtless he is acquainted with primary battery installations which have ended in disastrous failure, or he would not speak so positively. He deprecates the way in which batteries of all kinds are "puffed" as nauseating, and says that the depolarising agent is made a mystery of, and he evidently does not think that primary batteries will make a stir in house lighting.

Though not an electrician, I have had the honour to be acquainted and to work with those who have introduced primary batteries for lighting purposes to the notice of the public, and I am well assured that primary batteries, properly made and of a simple character, will light both mansions and smaller houses. I dislike speaking of myself, but I can say that part of my house has been lighted by a primary battery since August, 1884, and that no hitch of any appreciable kind has ever appeared so as to disgust me with primary batteries. I put the battery and the installation up myself with the aid of an intelligent man who works my steam engine, and this same man keeps the cells in order and attends to the lighting. My conservatory and a portion of the church are also lighted by primary battery.

The outside cells are of stoneware, and the manipulation of the battery is done without the aid of machinery, *i.e.*, by hand. This takes a certain time, and is reckoned in the cost of the lighting.

I use for my workshop small cells which illuminate a three-light chandelier. Nine of these cells were put under a severe trial by an electrician and chemist, with the result that they ran 3 15-volt 5 candle-power Edison-Swan lamps for 30 hours, the light at the commencement being exactly equal to 18½ candles, which sunk gradually to 12. The battery was then stopped, and a 10 candle lamp of low resistance worked for several hours more. The cost of working a 10-candle lamp, including the loss of zinc, was found to be 1⅕d. per hour, and less with larger cells. The size of the plates in the above battery—that is, of surface exposed—was, carbon 5½ × 6, and zinc 6 × 6.

The cost of the light competes fairly with candles, but is much higher than gas.

Every day sees some improvement in the cost of primary batteries, and more people are learning to know the difference between a toy and a battery which really is of practical use. There is no mystery about my depolariser, which is chromic acid, and there are no fumes. Possibly another day the utilisation of the "bye products" may cease to be a dream; at present I use the spent liquid as a disinfectant and deodoriser.—Yours, &c., CHARLES PENRUDDOCKE.

Nov. 30th, 1887.

PRIMARY BATTERIES FOR HOUSE-LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your correspondent, Mr. Thompson, appears by his comments on my letter to have misapprehended its purport, which was to answer a definite fallacy frequently repeated by objectors to primary batteries; and he may possibly not have been present at the meeting at which Mr. Perry Nursey's paper on "Primary Batteries" was read and discussed, for Mr. Nursey guardedly introduced his subject by pointing out that "*as regards small installations* the steam-driven dynamo-electric system still leaves a very wide and remunerative field open for a cheap and efficient primary battery;" while, in the discussion which ensued, one of the speakers questioned whether any battery consuming zinc could be used as a source of electricity excepting for purposes in which expense is not a matter of moment, and hazarded the assertion that "at a cost considerably under one halfpenny we could by the agency of the steam engine obtain one horse-power hour," which I impugned as a misleading statement, so far as it affects the comparison between steam engines and Mr. Nursey's ideal "cheap and efficient battery" for house-lighting purposes and small installations.

In taking exception to my observation that 2d. is not the whole of the daily cost of one electrical horse-power obtained from a steam engine and dynamo, since "the wages of one mechanic would alone amount in small installations to more than the whole cost involved in the use of a primary battery," Mr. Thompson puts the dots on my i's and crosses my t's. He writes: "Let us see how it works out for a user of, say, sixty-two lamps of 60 watts each," and proceeds to show that the wages of one engine-driver earning 30s. a week, divided over the work of an engine supplying five electrical horse-power, would make the additional charge to which I specifically referred 2d. per horse-power hour, or 4s. 2d. per diem, for this one man; but what would be a small installation for an engine and dynamo would not be called small if applied to a primary battery.

There are many houses in London which would be amply supplied with electricity without requiring more than one horse-power, or sufficient to light simultaneously 24 lamps of 10 candle-power, which in most cases would allow of double that number being distributed in different rooms, where they need not all be lighted at once. The charge for the same engine man, if applied to one electrical horse-power instead of to five, would be five times that 2d., or 10d. per horse-power per hour, and if to a ½ horse-power double that, or 1s. 8d., and so on, which exactly corroborates the statement in my letter.

Moreover, the installation of an engine and dynamo supplying five electrical horse-power is very costly, which acts as a deterrent with many individual consumers, and finally, such an engine could not be used at all where in London a primary battery is most often wanted, namely, in the cellar, or some other out-of-the-way corner of a house.

It is plain, therefore, that pending the general introduction of central stations thousands of householders who would gladly adopt incandescent electric lamps on sanitary and decorative or other grounds will be debarred from doing so if indiscriminate opposition to all primary batteries by the leaders of scientific opinion should become to be regarded as the only "good form." Mr. Preece's remark that "those gentlemen who were striving to introduce primary batteries for domestic lighting had an almost herculean task in hand" is only too true, for in such a matter the public is necessarily guided by the men of light and leading; but, in my opinion, none should be more desirous than the great electric lighting companies to encourage the gradual introduction by such means of a general taste for the beauty and hygienic superiority of incandescent lighting. Just as macadamised roads succeeded rough tracks, and in their turn were in due time superseded by railways, so also would it be with the electric light, and, with the experience of the last four or five years to illuminate our judgment, I venture to prophesy that without some such preparation of public opinion and taste the youngest man amongst us will hardly live to see the merits of central stations with dynamos and steam engines fully and universally appreciated. Electricity in its practical applications is still in its infancy, and we are about where the travelling public was in regard to roads a hundred years ago.—Yours, &c.,

Relf-road, East Dulwich. O. C. D. ROSS, M.I.C.E.

P.S.—If Mr. Thompson will take the trouble to re-read my letter he will see that I estimated the consumption of zinc, not at one but at two pounds per electrical horse-power per hour.

THE SCHANSCHEIFF PRIMARY BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In Mr. W. H. Preece's report on the Schanschieff battery, no mention is made by him as to the cost of the fluid to the users of this battery. He states that he has been testing and examining the battery for several months, and that a very accurate series of measurements were made with a battery

Digitized by Google

which produced one candle-power light for eight hours at a cost of materials consumed of 1d., and we are further told that the residue of this battery can be sold in the market or sent back to the Schanschieff Company, who will recuperate it and take in exchange in part payment for additional solution.

Now, Sir, this sounds very well to the uninitiated, but what we require to know is :—

Firstly. What is the cost of the Schanschieff fluid per gallon ?

Secondly. What quantity of fluid is wanted to run, say, a 5 candle-power lamp for eight hours consecutively, or intermittently?

Thirdly. What amount will the manufacturers allow for the spent fluid when returned to them ?

Fourthly. Who defrays the cost of carriage to and from the manufacturers ?

Fifthly. Where can the residue be sold in the market, who are the likely buyers, and at what price per gallon ?

Perhaps those gentlemen mostly interested in the Schanschieff battery will answer these questions, as they seem to me to be of more importance than the question whether the battery consumes an ounce or two of zinc more or less.

The transport of fluid from the consumer to the manufacturer and *vice versâ* must of necessity be a heavy item, and should be added to the cost of the light. One gallon of fluid by the various parcels deliveries in London, at from 6d. to 8d., and from London to the country from 8d. to 1s. 6d. the gallon, according to the distance. It would cost either the consumer or the manufacturer from 1s. to 3s. per gallon for carriage for the double journey, and more if it were sent over 400 miles.

In the interest of primary battery inventors, I should like to know what Mr. Preece has to say to this.—Yours, &c.,

Denmark-hill, S.E., Nov. 29th, 1887. W. E. Moser.

PRIMARY BATTERIES.—Mr. WEBSTER'S CHALLENGE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir : Mr. Wm. Webster, jun., challenges any primary battery inventor or maker to compete with the Holmes-Burke battery, in which he is interested, on conditions which are too restricted to be a practical test of superiority. First, because the competitor is to construct a battery with cells precisely similar in size and number to those he employs, thus excluding, amongst others, all users of round cells ; and, secondly, because the competition would exclude the consideration of at least two all-important points in domestic lighting, namely, the generation of more or less noxious, or inodorous fumes, and the "creeping" which is believed to be inseparable from all batteries using salts, but which hardly becomes seriously noxious until after a rather longer period than 14 days.

I am prepared to accept a challenge with respect to the comparative efficacy of the batteries if these and any other indispensable considerations are included, and am willing, with your consent, if Mr. Webster will do the same, to place a battery in your hands and under your control forthwith (five minutes will suffice to teach your office boy how to manage mine), if you will undertake to determine their comparative correspondence to what were enumerated as the "leading conditions which a primary battery for home-lighting purposes should fulfil" in the paper recently read by Mr. Perry Nursey before the Society of Engineers, Mr. Webster being only restricted to a battery of equal bulk and of a similar number of cells to mine.

I exact no forfeit from him in the event of your decision being, as I anticipate, against him ; but in order to facilitate the examination of the several points omitted in Mr. Webster's conditions, I must limit the size of the batteries to such as you can conveniently place on a table in your office, and would suggest for your convenience that if either of the two batteries should be declared by you to be in any way obnoxious or unpleasant it shall be at once removed, you being accepted as the arbitrator, and your decision as to their comparative merits final.—Yours, &c., O. C. D. Ross.

P.S.—Reporting on the working of my battery after a prolonged examination, Dr. John Hopkinson, F.R.S.—whose authority will hardly be questioned—pronounced that "the liquids used in the cells are less expensive than in any battery having any pretence to constancy." But I readily recognise that the solution of nitrate of soda used in the Holmes-Burke battery (which I have not the slightest wish to disparage) may be almost, if not quite, equally inexpensive.

TO THE EDITOR OF THE ELECTRICIAN.

Sir : I have always believed in the old maxim that "Charity begins at home," and I therefore confess that I should be much pleased to be able to secure Mr. Webster's £25, and thus enable me to give my *employés* a little Christmas treat, the same being derived from a public primary battery competition. So, if Mr. Webster will consent to send 12 guineas to the Editor of the *Electrician* and 12 guineas to the Editor of the *Electrical Review*, with instructions for those gentlemen to hand over 15 guineas of the amount in case his battery is knocked out of time, I will then accept his challenge on behalf of a battery I will produce.

As Mr. Webster's conditions are somewhat vague, I would suggest that the articles and conditions of competition be as follows, the tests to be made with a battery, say, of one or any number of cells up to sixteen, containing 2 gallons of solution in each cell.

I mention 16 cells as the maximum because it is a useful number of cells to feed ten 10 candle-power lamps of 15 volts, coupled two in series according to resistance, or half the number of 30-volt.

Lighting Test.

(1). One or two cells to run a single 2 or 4 volt lamp of 1 or 2 candle-power, with elements kept in solution, and not touched under any conditions until cells are fully exhausted and light out, when zincs should be reweighed and cost noted.

(2). Four cells for running a single 8-volt lamp of 5 candle-power, under precisely similar conditions.

(3). Sixteen cells for feeding the greatest number of lamps the battery is capable of sustaining for runs of six hours per day until exhausted and lamps out. To commence at 12 o'clock, close at 6 daily.

For Power Purposes.

(4). A 2 or 3 cell complete battery and electric motor for driving a sewing machine of any known type until battery is fully exhausted, speed of machines to be taken alternately every half hour.

General Conditions.

(5). The batteries for each installation, Nos. 1, 2, 3, and 4, to be enclosed in sealed cases with the seal of each party, and testing room to be locked up during intervals.

(6). Each party to be allowed one assistant to be present during hours of competition, to watch and take notes.

(7). A test room to be rented for the purpose in the City, for competition, within easy distance of the arbitrators' offices, who shall be at liberty to go into the testing room at all times they may think fit during competition; but no other person to be allowed to enter the room except the competitors, their assistants, and arbitrators.

(8). The rent of testing room and other expenses to be equally divided by competitors.

(9). Some electrician to be appointed by the two arbitrators, whose business it shall be to take the half-hourly readings, speed, &c., of machines running on behalf of the arbitrators.

(10). Lamps to be used to be either "Shippey's" compound metaloid filament, or Swan carbon filament, at Mr. Webster's option ; but in each case the lamps supplied for the test shall be sent to the arbitrators with voltage duly marked thereon, and all lamps shall be put into a box, and each competitor to select a lamp from general assortment until the quantity of same are equally divided.

(11). The arbitrators to decide on testing appliances to be used, and also be allowed to add any other conditions they may think necessary.

(12). Each party to be bound by the arbitrators' decision, which shall be final.—Yours, &c., Arthur Shippey.

13 and 14, King-street, Cheapside, London, E.C.,
30th November, 1887.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

At the ordinary fortnightly meeting of this Society, held at the Institute of Civil Engineers, on Thursday, the 25th inst., the PRESIDENT (Sir Charles Bright) in the chair, a paper was read on "Some Instruments for the Measurement of Electromotive Force and Electrical Power," by Dr. J. A. FLEMING and Mr. C. H. GIMINGHAM. This was followed by a paper on "Portable Voltmeters for Measuring Alternating Potential Differences," by Profs. W. E. AYRTON, F.R.S., and JOHN PERRY, F.R.S.

[Owing to the numerous drawings with which these papers were illustrated, we are unable to reproduce them in the present issue. The following brief account of the instruments is sufficient to give a general idea of their construction.]

The voltmeters of Dr. Fleming and Mr. Gimingham are based upon the electro-dynamometer principle, and they are therefore available for alternating currents. The chief feature of these instruments consists in the employment of a pair of solenoids arranged parallel to one another, and so wound that they exhibit the same polarity at each end, with a consequent pole at the middle. Each of these solenoids is encircled at the centre by a narrow ring-shaped coil of somewhat larger diameter. These two latter coils are connected by a light cross bar, to the centre of which is attached a spiral steel spring by which they are suspended. The internal diameter of the ring coils exceeds the external diameter of the solenoids sufficiently to permit of some deflection. The coils are brought back to the zero position by means of a torsion screw attached to the suspending spring, as in the Siemens dynamometer. Several very beautiful and ingenious refinements of detail have been introduced, which can only be appreciated from a detailed description and drawings of the instrument. The dials are graduated, so that the instruments are direct reading and require no table of square roots.

The new voltmeter of Profs. Ayrton and Perry is based upon the well-known Cardew instrument. The chief object of the new arrangement is to render the instrument more portable, more constant, and more reliable in the readings of the lower part of the scale. For this purpose the platinum wire employed is only a few inches in length. It is placed horizontally, and is attached rigidly at both ends. The sag of the wire increases with the difference of potential at its terminals. To render this apparent, to the centre of the wire is attached a spring of the same description as those constructed by the authors for their well-known "spring" ammeters and voltmeters. By this means the objects aimed at have been most effectually secured, but numerous modifications and refinements of detail must be left for description in the complete paper.

DISCUSSION.

Mr. GORDON said it was not his intention to criticise the beautiful instruments on the tables before him devised by Prof. Fleming. He felt how much they owed to those who devised instruments for the practical measurement of volts, and how important it was that every practical difficulty should be eliminated. What was wanted was a voltmeter that could be as easily read as an ordinary steam gauge; they wanted voltmeters not only that skilled electricians could read, but that a driver at 30s. a week could be trusted to attend to. They wanted something extremely simple and easily looked after. For these reasons one or two criticisms occurred to him on Prof. Fleming's paper. In the first place, the dial ought preferably to be vertical rather than horizontal. They could not get a man to effectually watch all night fifteen or twenty horizontal dials. If he dozed off for a minute he could not notice them. He was constantly stooping over the table, and an instrument whose dial was placed vertically was decidedly preferable to one placed horizontally. With regard to the Cardew voltmeter, it was very satisfactory to see such a beautiful development of Captain Cardew's principle as Prof. Ayrton had shown them. But they must not forget how much they owed to Captain Cardew for having given them the principle. They must remember that was not a mere theoretical principle. His own experience of voltmeters had been this. For eleven months he had eighteen instruments. These required a great deal of attention in graduating them. They always found it necessary to keep the current on at least two or three days in order to get rid of any permanent sag. They did not trouble about the zero. He had found it convenient to take the liberty with the instrument of taking off the dials and pivoting them, and they arranged they should be able to turn the dials 30 or 50 degrees. They simply put it on the same circuit as the standard instrument, and then turned the dial till 120 volts on the dial came to where the needle was. They set the instruments every morning in this way. As to the differences of sensibility, they tried many means. There was a very important point in Prof. Ayrton's instrument. It was the only voltmeter he had seen in which there was no current in the spring, and for that reason he did not see how there was any possible source of error. In the engine room they did not care a bit whether ten volts or twenty volts could be read correctly, but it was important whether they got 110 or 111 points, and he would like to ask this question, Whether by increasing the sag or by any alteration of the sag they could make the instrument more sensible at one particular point—say, 120-volt point. He expressed the great interest he had felt in the description of the development of Captain Cardew's principle.

Captain CARDEW, in the course of a few observations, said he had seen Prof. Ayrton's pretty instrument for the first time that day. As to his own instruments, he thought he might say that since Mr. Gordon took the voltmeters in hand, they had improved very much, the greatest care having been paid to manufacture. They were totally new instruments. In concluding his remarks Captain Cardew described on the black-board a voltmeter of a standard form which, he said, anybody could make for himself.

At this stage Mr. PREECE suggested that as the papers were of great interest to many the discussion should be postponed. There was an instrument on the table they were all anxious to hear described, and he hoped the author of it, Prof. Forbes, would be induced to renew the discussion that night week.

Before the meeting was adjourned Prof. AYRTON, in reply to Mr. GORDON, said his voltmeter could be used in a vertical as well as in a horizontal position.

PHYSICAL SOCIETY.

At a meeting of the Physical Society, held on November 26, 1887, Dr. Balfour Stewart, President, in the chair, a paper was read by Prof. S. P. THOMPSON, D.Sc., on

THE ANALOGIES OF INFLUENCE MACHINES AND DYNAMOS.

The author pointed out that in nearly all influence machines there are two stationary parts ("inductors") electrified oppositely—which are analogous to the field-magnets of dynamos—and a revolving part carrying "*sectors*," which corresponds to the "*sections*" of an armature. To prevent ambiguity, Prof. Thompson proposes to call the inductors "*field-plates*," and the revolving parts as a whole an *armature*. In the Wimshurst machine both field-plates and armature rotate, and each acts as field-plates and armature alternately. In the two-field-plate influence machines there are four, and sometimes six brushes. Two of these act as potential equalisers, two as field-plate exciters, and the remaining two (if any) are generally placed in the "discharge" or external circuit. The Holtz machine having only four brushes, two serve the double purpose of potential equalisers and discharge circuit, and this machine excites itself best when the discharging rods are in contact. In this respect it resembles a series dynamo, which only excites itself when the external circuit is closed, but on opening the circuit (say by inserting an arc lamp) produces remarkable effects. So in the Holtz machine, on separating the discharging knobs a shower of sparks results. The Toepler machine (made by Voss), having six brushes, resembles a shunt dynamo and excites itself best on open external circuit. Analogies were traced between Thomson's replenisher and the Griscom motor. An example of an analogue to the compound dynamo was mentioned as existing at Cambridge in the form of a Holtz machine, believed to have been modified by Clerk Maxwell. Another analogue with dynamos is found in the displacement of the electric field when the armature is rotated, just as the magnetic field of a dynamo is shifted round in the direction of rotation. Further analogies were traced between "critical velocity" of dynamos (which depends on the resistances in the circuit), below which they do not excite themselves, and a similar critical velocity of influence machines; *e.g.*, in a Wimshurst or Voss machine the potential equalising circuit should have a low resistance if it is to excite itself readily. Self-exciting dynamos excite better when the iron is bad and retains the magnetism, and influence machines excite better when the field plates are made of paper, or such substance as can well retain a residual charge. Both dynamos and influence machines can be reversed and used as motors.

Influence machines may also be classified by their analogy with the drum, disc, and pole armatures respectively, but there is no analogue to the ring armature of a dynamo. The Clark gas lighter is a good example of a drum armature, and a diagram showing the internal arrangements was exhibited. After mentioning that the earliest rotary influence machine, Nicholson's revolving doubler, was simply a kind of revolving electrophorus, the author pointed out that metal plates passing each other with only air between would never make a good machine, as there would be a discharge through the air which would prevent the continuance of self-excitation. There should always be two sheets of glass or other dielectric between the relatively moving conductors, as if there were one only it would be discharged upon. He also observed that for an influence machine to excite itself readily it must have a good metallic working circuit. This condition is fulfilled in the Wimshurst machine, and Prof Rücker mentioned that recently, on the occasion of a visit from Mr. Wimshurst, it was found that the large machine which the inventor had presented to the Science Museum excited itself readily, though it had been left untouched for over a year.

Digitized by Google

Mr. H. Tomlinson then showed some interesting experiments

On the Thermo-Electrical Properties of Iron.

The author finds that if one of the junctions between strained and unstrained portions of an iron wire be gradually heated up to bright redness, the current, which flows from unstrained to strained wire across the hot junction until this temperature is reached, then suddenly changes to the opposite direction. A secondary effect observed by the author is of considerable interest. If the gas flame be slightly shifted while a small portion of wire is at a bright red temperature a current is produced incomparably stronger than those usually observed, its direction depending on that in which the flame is shifted. This current is clearly due to an inequality of temperature between the two junctions of red hot with comparatively cool wire. It appears to the author that this may very possibly be due to the total absence of strain in the molecular condition of the red hot wire, while the cool wire must necessarily be in a state of more or less molecular strain, owing to the contraction which takes place on cooling.

THE BRUSSELS EXHIBITION.

Extract from the Prospectus.

Under the patronage of His Majesty the King of the Belgians, the honorary presidency of H.R.H. the Count of Flanders, and with the active support of the Belgian Government and the city authorities, it has been decided to hold an International Exhibition at Brussels from May to October, 1888. * * * * *

A special arrangement of an exceptionally favourable character has been made with regard to the British Empire Section, which will occupy an unique position in the best portion of the grounds, and be under the exclusive control and management of Mr. S. Lee Bapty, at present general manager of the Royal Jubilee Exhibition, Manchester, the splendid success of which speaks very highly for his great capacity for organisation and ability to conduct a similar undertaking to an equally favourable issue.

In the British Section it is especially desired to illustrate as fully as the space allotted will admit the vast resources of the great empire which it represents, particular regard being had to those products and manufactures which are most suitable for the Belgian market.

In addition to gold, silver, and bronze medals, exceptional inducements are offered to exhibitors, a sum of 500,000f. having been set aside for distribution in special prizes, particulars of which will be duly announced, and it is also intended to have a grand prize distribution of some millions of francs after the manner of the Art Union, all the articles in which must be purchased from the exhibits in fair proportion.

The time at disposal being comparatively short, it is earnestly requested that application for space may be sent in immediately.

SOME PROPOSED BILLS FOR NEXT SESSION.

The South Metropolitan Electric Supply Company (Limited), whose office is at Winchester House, Old Broad-street, notify their intention of applying to the Board of Trade on or before the 21st proximo for a provisional order under the Electric Lighting Act, 1882, authorising the company for such period as shall be prescribed to produce, store, sell and distribute electricity for public and private purposes within the following area :—The City of London and the liberties thereof, and the following parishes or places in the county of Middlesex, viz., St. Anne, Soho ; St. Paul, Covent Garden ; St. John the Baptist, Savoy, or Precinct of the Savoy ; St. Mary-le-Strand, St. Clement Danes, Liberty of the Rolls, the parishes of St. Giles-in-the-Fields, St. James, Westminster ; St. Martin-in-the-Fields, St. Margaret, Westminster ; St. George, Hanover-square ; St. John the Evangelist, Westminster ; together with the extra-parochial places known as Staple Inn, Lincoln's Inn, the Temple, the Close of the Collegiate Church of St. Peter, and the Victoria Embankment of the River Thames, also all or some of the parishes or places in the county of Surrey following—that is to say, St. Mary, Lambeth ; St. George the Martyr, St. Saviour (including the Liberty of the Clink), and Christ Church. The company will ask for powers to construct and maintain on lands to be acquired or leased by them within the area of supply "such central and other stations and works for the generation, storage, supply, and distribution of electricity and electric currents, as may from time to time be necessary for supplying electricity within the said area, or for the other purposes of the order," together with all buildings, engines, &c., necessary or convenient, and to lay down, maintain, &c., electric lines, mains, &c., for the supply and distribution of electricity and electric currents in the area mentioned. By other clauses the company will ask to be empowered to "open and break up streets, &c., to purchase or acquire by agreement lands and houses, and also patent rights and licences or authorities for the use of inventions or protected processes relative to the production, supply, and distribution of electricity, and to manufacture, purchase, hire, and supply meters, lamps, appliances, machinery, and apparatus for and in relation thereto ; to make charges and levy rates, &c., for the supply of electricity ; to exempt the company from the obligation to supply electricity under circumstances specified or provided in the order, and to confer on the company the powers of the Electric Lighting Act, 1882, and any Acts amending the same, and such other powers, &c., as may be necessary or expedient for carrying out the purposes of the order, which will define and limit the prices to be charged."

The United Telephone Company (Limited) will apply to Parliament in the ensuing session for an Act conferring on the company, or a company to be incorporated, powers to carry wires for telephonic communication over, along, or across any highways, streets, &c., and any houses or lands within twelve miles of the General Post Office, and within all other parts of the county of Middlesex, and giving vestries and other public bodies and companies powers to enter into agreements for facilitating telephonic communication. The Act will contain clauses giving powers to break up streets, erect posts on, and lay or carry wires for telephonic communication under or over any land, house, street, or other place within the limits mentioned, on such terms and conditions as may be from time to time prescribed by the Board of Trade, the Metropolitan Board of Works, the Commissioners of Sewers of the City of London and the liberties thereof, or other public authority, or otherwise as shall be provided by the intended Act, for the purposes of which authority will be asked for the company or the new company "to acquire, sell, manufacture under, or otherwise use any patents and licenses for the transmission of telephonic communication, and also to grant licenses to manufacture under, or use any such patents either within or without the limits aforesaid." Authority will be asked "to make, levy, and recover rates, rents, and charges," and to grant exemptions from such payments, and to make and enforce bye-laws, and to impose penalties. If found necessary or desirable the company will be dissolved, and the shareholders reincorporated with other and extended powers.

Application is intended to be made by the Society or Corporation called Lloyds for an Act empowering them to erect, maintain, and work signal stations, with all requisite telegraph and telephone wires, posts, &c., on the coast of Great Britain and Ireland, and the islands appertaining or belonging thereto, as shall be thought expedient and necessary for the preservation of life and property. The Act will also ask for powers to place and maintain posts, tubes, and wires "over or under any lands, houses, buildings, or water which may intervene between any such signal station, or signal house and any post office, telegraph station, or public highway, for the purpose of affording or completing means of telegraphic, telephonic, or electrical communication."

The Great Western Railway Company have given notice of their intention to apply for Parliamentary powers for the construction of a tramway from Oxford to Brill, "to be worked by electrical or mechanical power."—A notice issued in the name of the "Eastern and Midlands Railway" describes several tramway lines in the county of Norfolk, for which powers are to be obtained to work by "electrical or mechanical power."

The Corporation of Liverpool will apply to the Board of Trade for a Provisional Order granting powers for the use of "electrical, steam, or other than animal power" on certain portions of their tramways.

The Corporation of Bradford will apply to the Board of Trade for a Provisional Order authorising the construction of tramways in the borough, and the use of "steam or other mechanical power, or electricity," on them.

The Llanelly Local Board of Health announce their intention of applying to Parliament for an Act, by clauses in which the Board will ask for authority to control, and, if need be, to prohibit the placing of "any wire, tube, or other apparatus for telegraphic, telephonic, electrical, or other purposes," over any public thoroughfare, except with the consent or license of the Board, and on such conditions as they shall deem expedient to prevent danger or annoyance to the traffic or to passengers. The Board will also ask for powers to inspect such apparatus, and to order its repair, alteration, or removal, and in default to be enabled to execute the requisite works themselves at the cost of the owner or hirer ; and they will further ask to be relieved "from all liability by reason of any failure of or accident from any such wire, tube, apparatus, or works."

In the Bill for which the Corporation of West Ham will apply to Parliament, powers are asked for to regulate, and, if thought fit, to prohibit the placing and maintaining of posts, wires, conductors, cables, &c., over, along, across, or beneath streets or other places within the borough.

A Bill will be applied for incorporating the Margate Tramways Company with powers to construct tramways, and with authority to employ on them "animal, steam, electric, or other mechanical or motive power."

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

16,032. W. MAIN. London. Improvements in electromotors and dynamo electric machines (complete specification). November 22, 1887.

16,058. G. F. REDFERN. London. Improvements in and relating to telephonic apparatus (Seonce de Combettes, France). November 22, 1887.

16,087. J. S. FARMER Manchester. An electric contact maker, particularly applicable for use in conjunction with coin freed apparatus. November 23.

16,120. E. TYER. London. An improvement in voltaic batteries (complete specification). November 23.

16,128. W. H. MUNNS. London. Improvement in mechanical telephones (J. P. Sunderland and D. M. Monjo, United States). November 23.

16,134. T. J. JONES. London. An improvement of voltaic batteries. November 23.

16,185. W. J. S. BARBER-STARKEY. London. Improvements in electric motors. November 24.

16,217. F. C. ALLSOP. Kent. Apparatus for automatically conveying and delivering letters and small parcels by electricity. November 25.

16,228. W. F. C. WARD and E. W. WILLEY. London. Improvements in arc lamps for electric lighting. November 25.

16,296. A. FRENCH GEORGE and C. R. BONNE. London. Improvements in primary and secondary galvanic batteries. November 25, 1887.

16,325. F. T. SCHMIT. Yorkshire. Improvements in electrical switches and cut-outs. November 28.

16,333. A. B. O'CONNER and G. W. BUTTERFIELD. London. A mechanical appliance adjustable for clocks, watches, locks, railway switches, electric lights, gas lights, and other machinery, regular periodic application of power for adjustment. November 28.

16,351. A. OWEN. London. Improvements in electric belts (complete specification). November 28.

COMPLETE SPECIFICATIONS ACCEPTED.

NOTE.—*All persons interested in opposing the grant of a patent on any one of the undermentioned applications may, at any time within two months from the dates in italics, give notice at the Patent Office in the prescribed form of such opposition.*

November 26th, 1887.

275. R. E. B. CROMPTON and J. H. F. SOLL. London. Improvements in and apparatus for effecting the distribution of currents of electricity. *January 7, 1887.*

1,331. D. HALPIN and I. A. TIMMIS. London. Improvements in commutators, brushes, or contact pieces for electrical apparatus. *January 27.*

November 30th, 1887.

1,176. J. HARRINGTON. London. Improvements in musical instruments or chiming apparatus, the hammers of which are operated by electricity. *January 25.*

1,499. T. O. CALLENDEN. London. Improvements in laying and insulating underground wires intended for use as conductors of electricity.

11,200. A. J. BOULT. London. Improvements in electricity-controlled unison motors (J. F. McLaughlin, United States). *August 16.*

13,778. W. WALKER. London. Improvements in automatic electric signalling for railways and apparatus therefor. *October 11, 1887.*

PATENTS SEALED.

November 22, 1887.

14,757. W. LAHMEYER. Germany. An improved dynamo electric machine. November 13, 1886.

14,765. C. L. BOWDEN. Cheshire. Improvements in dynamo electric machines and electric motors. November 15, 1886.

11,129. H. COLLETT. London. Improvements in electro magnetic telephones. August 15, 1887.

11,188. H. H. LAKE. London. Improvements relating to the conversion of chemical energy into electrical energy, and to apparatus therefor (W. Erastus Case, United States). August 16, 1887.

11,189. H. H. LAKE. London. Improvements in apparatus for the conversion of heat into electrical energy (W. Erastus Case, United States). August 16, 1887.

November 25, 1887.

7,720. S. S. BROMHEAD. London. An improved telephone switch (C. A. Hitchcock, United States). May 27, 1887.

10,716. T. M. KNIGHT. Improvements in electric alarm apparatus. August 4, 1887.

SPECIFICATIONS PUBLISHED DURING THE MONTH.

17,084, 1886.—A. R. BENNETT. Board for mounting telephone switches, etc. (Price 6d.)

5,292, 1887.—J. H. ALLISON. (The Baxter Electric Manufacturing and Motor Co.) Electric Motors. (Price 8d.)

13,245, 1887.—E. GRAEFE. Placing railway trains in communication with an electric conductor, separate therefrom. (Price 6d.)

LEGAL INTELLIGENCE.

Callow v. Young.

The defendant in this case was, upon the application of the plaintiff, ordered to be committed to prison for breach of an undertaking whereby the defendant undertook by his counsel not to, within 100 miles of the Royal Exchange, London, carry on or be directly or indirectly concerned in the business of a telephone manufacturer. The undertaking was embodied in an order of the Court, and the solicitors of both parties signed the registrar's book. The defendant, however, secretly carried on the prohibited business by means of using the name of a third person. The defendant was cross-examined in court.

Mr. Romer, Q.C., and Mr. Oswald appeared for the plaintiff.

Mr. WRIGHT TAYLOR, for the defendant, submitted that there was nothing to show that the defendant had had any knowledge of the undertaking given in his name.

Mr. JUSTICE CHITTY, in making an order as asked, said that the defendant had given an undertaking and deliberately broken it, and, as the rights of suitors must be protected, he had no other course than to make an order. He was very unwilling to accept an uncorroborated statement by a man that he was unaware that he had given an undertaking such as that given in the present case, for it was the duty of his legal advisers to communicate with him, and it was to be presumed that the ordinary business course had been followed.

COMPANIES' MEETINGS.

The German Union Telegraph and Trust Company (Limited).

An extraordinary general meeting of this Company was held on the 28th ult., at Winchester House, Old Broad-street, for the purpose of considering a report of the Directors, and determining as to proposals made by the Imperial German Government for the acquisition of the cables and property of the German Union Telegraph Company (of Berlin). Sir James Anderson presided.

The SECRETARY (Mr. Wm. Payton) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen—I propose giving you as clear a statement as I can of the circumstances which are leading to the sudden termination of the existence of this Company—a company which, until very recent days, I regarded as likely to retain the position of doing all the submarine cable work which Germany might desire. A few weeks ago two of the leading officials of the German Postal and Telegraph Department were in London, and I believe it was then decided that Germany and the English Post Office would either acquire the existing cables or lay their own cables, and that the two Government Telegraph Administrations would work the traffic at a reduced tariff. The German Government could not of course cancel our concession, which has still eleven years to run; but this concession is not exclusive. It is worked in concert with the German Telegraph Administration. We have also agreements with the Submarine Telegraph Company, whose concessions end next year, and with the Anglo-American Telegraph Company. This latter agreement will be taken over and carried out by the German Telegraph Administration. In the latter days of October the Berlin Board of the German Union Company were called upon to negotiate for the sale of the Company's cables, or to submit to the opposition of Government rival cables, at a tariff which, even with a large amount of traffic, would have given us a very small revenue. These negotiations were carried on by Dr. Lasard, the Managing Director in Berlin, and I must say very ably carried on, and practically the result is that we are offered the first cost of the cables—one of which is seventeen years old—and we are allowed to retain our reserves. We are called upon to reply promptly. It must be admitted, as claimed by the German Government negotiators, that a sum of money offered by Germany for our property—£315,000—which, together with our reserves and the interest for 1888, would yield, if invested in German Rentes, 4 per cent. interest in perpetuity on the original share capital, cannot be called inequitable. But you will naturally say, "That is all very well for the original shareholders of the German Union Company, but what about the German Union Trust, of which we are shareholders, and who do not get par for their shares?" Well, gentlemen, I have to tell you that the German Government never recognised this Trust Company, and do not now recognise its existence, although we have always acted as the London agents of the Berlin Company. For about two years after the German Union Company laid their cables the capital was all in the hands of a few bankers and their friends, and in order to obtain a quotation on the London Stock Exchange an English Trust Company was formed, and those who had risked their money and worked the cables for about two years, and who had concluded valuable agreements, considered that they deserved some profit for their risk and labour. I beg to say I was not one of that happy number. When I joined the Company I paid £2 premium for my shares, and I considered the Company would turn out prosperous and be likely to extend its useful-

ness, as it has done, paying a dividend of nearly 6 per cent. since the commencement upon the increased capital. The original shares were £15 per share, and when this Trust Company was formed the nominal value of the shares was made £20 in two £10 shares. The amount of money now offered to us is sufficient with the reserves, interest, and dividend of 1888, to give us about £19 on the original shares of £15, and £9. 10s., or a little more, upon the shares of this Company. Of course, as the money will not be paid until January, 1889, and as there may be repairs, or accidents in the interval, the exact amount cannot be estimated accurately; but £9. 10s. to £9. 15s. is the present estimate, allowing for the usual expenses: and you must understand that these sums are made up by including next year's revenue, and as I have already said reserves and interest, and, in fact, all our resources. Therefore, after the dividends which are intended to be paid, as usual, in January and March next, there will not be any more interest, but simply a return of capital in January, 1889. I may remind you that all the Trust shareholders had an opportunity of subscribing for preference capital, and the majority of the shareholders so acted, so that all who did so will have a fair average return on their investment. I must say our first impression of the amount offered was disappointing, nor did we like the extreme urgency, as it did not give us par for our Trust Company's shares, nor adequate time to consider the proposition, and I went to Berlin, accompanied by Count Reichenbach and Mr. Payton, your secretary, to see if anything could be urged to improve the position, but the Director-General of Posts and Telegraphs, who is *ex-officio* a member of the Council of Supervision which controls the German Board of Direction, very definitely said, "There is the proposition, and I am instructed to urge its prompt acceptance, or we will lay our own cables." We have therefore returned with the conviction that it is to your interest to give us the power to accept the offer of the German Government. I may say that the Globe, which holds half the capital, have agreed to accept. This power must leave here to-night to be in time for the general meeting in Berlin on the 1st December, and the reason for this urgency I understand to be the necessity of including the amount I have named in the Budget to be presented next month in the Reichstag; or alternatively some other sum for new cables, if we decline. With these remarks I will move the following resolution:—"That the Board of Directors be and they are hereby authorised to agree on behalf of this Company to the terms proposed by the Imperial German Government for purchase of the cables and property of the German Union Telegraph Company of Berlin, and to take all such steps as they may deem necessary or expedient to have such purchase completed."

Count REICHENBACH seconded the motion.

Mr. W. GRIFFITH said he did not blame the German Government for making the proposal, for they were men of business and could see that the property they wished to acquire was a very valuable one. For that reason, however, he contended that a better price ought to be given.

Mr. S. LOWENTHAL (Brighton) acquiesced in this view, and said that his case was a very hard one. He had been a shareholder from the inception of the Company, and regarding the investment as such a good one he bought 75 more shares a fortnight ago, at something like £10. 12s. 6d. each. He had not yet got the certificate in connection with that transaction. Two or three days afterwards, however, to his astonishment, he received notice informing him of the negotiations for acquiring the property, and the shares fell to £9. 5s. He wished to know, in connection with that fall, if any of the Directors had sold shares after their cognisance of the negotiations.

The CHAIRMAN: Certainly not.

Mr. LOWENTHAL: Neither directly nor indirectly?

The CHAIRMAN: Neither directly nor indirectly.

Mr. LOWENTHAL, continuing, said he thought that the shareholders should have been made acquainted with the matter before. If necessary, he thought the Directors should appeal to the British Government in the matter.

The CHAIRMAN, in reply, said that the Directors knew no more about the matter than the man in the moon until about three weeks ago, when Dr. Lasard put before them the terms offered by the German Government, and it was—Take these terms, or we are determined to lay our own cables. That Government for some time had been in communication with the English Post Office and the other Governments—the Continental Governments—and had determined to have their own cables, to take over the concessions as soon as they expired—he meant the submarine cable concessions—and reduce the tariff. The tariff which would remain to the Company if they chose to continue working their cables would be a halfpenny a word, and if the cables were full that tariff would not do much more than pay working expenses. Moreover, they would have as rivals the English and the German Governments, a matter on which they had never been consulted. The shareholders could not, therefore, expect the Directors to go to the English Government and ask them to try and induce Germany to give them more money, when the English Government themselves were determined, having their own cables, to reduce the tariff. As a private company they would have to compete with two Governments, and work at a tariff of a halfpenny a word. The German Government maintained that they had offered a fair price for the cables in giving a sum which would return 4 per cent. in perpetuity if the money were invested in German Rentes. The Directors went to Berlin—disappointed, as the shareholders might suppose—at the beginning, and they said and did all they could; but it was of no use. The power of attorney had to go that night to Berlin, or their property would be practically worthless. That was the position which as Chairman he had to put before the shareholders, and he could not suppose that they would be so stubborn as to refuse the offer. He then put the motion, and it was carried with one dissentient.

In reply to a vote of thanks proposed by Mr. GRIFFITH,

The CHAIRMAN said: Our concessions have only eleven years to run, and what is the use of a tariff of a halfpenny a word?

The meeting then separated.

Blackpool Electric Tramway Company.

The annual meeting of the shareholders of this Company was held on Saturday, under the presidency of Mr. R. Horsfall, mayor of Halifax.

The CHAIRMAN pointed out that the Company had suffered an unfortunate mishap during the year in the failure of the line. This had put them to considerable expense in horse hire and in repairs, and then again they had had to contend against great competition from the omnibus proprietors. He complained that they were most unfairly dealt with by the Corporation of Blackpool, who allowed the omnibuses to run on Sunday, but prevented the tramcars from carrying passengers on that day. The old insulators were being replaced by new and more effective appliances, and after their experience of the past year he had increased confidence in the concern. No dividend was declared. A sum of £471 was carried forward to the reserve fund. Messrs. Kingsbury, Ormerod, Shaw, and Smith were re-elected Directors.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 25th November amounted to £4,431.

RAILWAY TRAIN TELEGRAPHY COMPANY (LIMITED).—With a capital of £3,000, in £1 shares, this company has been registered to "construct demonstrative lines of railway telegraph," with all necessary adjuncts, under patents granted to Thomas A. Edison, Ezra T. Gilliland, and Lucius J. Phelps.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 25th were £3,563, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Mr. William Abbott, of Tokenhouse Yard, London, desires to state that the use of his name by a firm assuming the title of Abbott, Page and Co., was totally unwarranted.

Mr. Rashleigh Phipps desires us to state that he has taken into partnership Mr. A. R. Dawson, late of the United Telephone Company, and Messrs. Judson's Electrical Works, Southwark, and that the style of the firm will now be Messrs. Rashleigh Phipps and Dawson, carrying on business at the same address, 185 and 187, Gray's Inn-road, where Mr. Phipps has so successfully carried on business as electric light engineer and contractor.

Messrs. Laing, Wharton and Down notify that after Saturday next, December 3, their address will be 82, New Bond-street, W.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 499.—Vol. XX. FRIDAY, DECEMBER 9, 1887. Price 4d.

NOTES.

This week we publish in another column the first of a series of New York letters, which will be continued periodically, and which we anticipate will furnish readers of *The Electrician* with the latest and most trustworthy information relating to the progress of electrical industries in America.

The *Gas World* is good enough to admit that the electric lighting industry progresses with "wond rful rapidity," and deprecates the ostrich-like policy of those who let their interests in the gas-distributing industry blind them to the advances of the rival illuminant. Nevertheless, it is satisfied that although the rivalry may be a real and serious thing one day, the day is as yet somewhere in the "unknown future." Our contemporary, however, goes on to say that "everyday experience teaches us new lessons," which is, or ought to be, conducive to modesty in forecasting the future. One of our own experiences just now has been the perusal of one figures compiled by the Bureau of Statistics in Berlin, from which we learn, among other things, that four-fifths of the steam engines now working in the world have been constructed within the last twenty-five years. Locomotives and marine engines are not included in the return, but exclusive of these England alone employs steam equivalent to 7,000,000 horse-power. If electricity is to progress with anything like the same "wonderful rapidity" we shall be content to regard the "unknown future" with resignation.

The subject of telephonic communication at sea, which has attracted additional interest in consequence of recent shipping disasters in the Channel, is rendered somewhat superfluous by Mr. Sedley Taylor's letter in *The Times* last Saturday. The detailed account of Colladon's experiments on Lake Geneva quite fifty years ago seems to indicate that the mere employment of a submerged bell or gong on the one hand, and on the other a trumpet-shaped tube with its broadest end immersed in the water, are sufficient appliances for the submarine transmission of sound to a distance of eight miles at least, even in rough weather. Reference to these experiments of Colladon's is to be found in several text-books on "Sound," and it is only surprising that the suggestion has not hitherto been turned to practical account. Recent experiments of the kind with the microphone and telephone seem to have been hitherto successful only to a distance of a mile—probably because these instruments are too sensitive, the true signal being overpowered by the disturbances of extraneous sounds close by.

Our recent article on the training of electrical engineers has called forth several communications, besides those we have published, from persons directly interested in the training of electrical engineers, among others from Prof. Garnett, of the Durham College of Science, Newcastle-on-Tyne, and from Mr. George Montefiore Levi, of the Institut Electro-Technique at the Liège University. From both places programmes are forwarded to us, showing that on the one hand mechanical engineers are required to go through a course of Electricity, and on the other that electrical engineers have to learn the principles and practice of applied mechanics. Of course, we were aware of this, our point being that the mechanics of the College cannot compare in usefulness with those of the practical workshop.

A writer in *Industries* (the abstract of whose valuable paper on "Central Station Lighting" will be found in another column) arrives at the conclusion that "electricians would be wise to devote their attention rather to the development of the battery system than to that of distribution by rotary transformers." Without going so far as to dispute this dictum we venture to think that the question will bear a little further discussion. In the particular scheme which the author has chosen for illustration the capital cost of the two systems works out in the proportion of 60 for batteries to 52 for motor generators. But the author very fairly points out that the omission of several important items, such as cost of land for the central station, and rental or purchase of premises for sub-stations, would go far to reduce this apparent superiority on the part of the motor-generators. So far, we are entirely with him, and we also agree in anticipating a decided reduction in the cost of batteries.

The divergence of our views from those of the writer in question commences at the point where he asserts that "it should be borne in mind that there is not much probability of the rotary transformer becoming cheaper in the future," on the ground that "it is nothing more than a dynamo with two circuits on the armature, and since the price of dynamos has fallen to what may reasonably be expected to be its lowest level it is difficult to see how rotary transformers could be further cheapened." The majority of our readers will not, however, experience this difficulty, inasmuch as we have quite lately de-

Digitized by Google

scribed and illustrated a system in which the rotary transformer—or, as we prefer to call it, the motor-generator—so far from being, as the writer estimates, 25 per cent. dearer than a dynamo of the same output, should be very little dearer than an alternating current transformer. We must refer the author to our previous issues for the details of this system, expressing, by the way, a mild astonishment that so careful and evidently well-informed a critic should yet have remained in ignorance of the work of MM. Jehl and Rupp.

It is not merely on the question of cost that the Jehl and Rupp system meets the most formidable objections of the critic. One point raised is that, owing to the noise and vibration of the armatures, it would be more difficult to find suitable localities for sub-stations on this system than when batteries alone are employed. This objection, of course, falls to the ground when the transformers remain at rest and a single, comparatively light commutator is alone in motion in each sub-station. We hold no brief on behalf of motor-generators, but we certainly think that the question must be reconsidered in the light of these facts before the conclusions set forth in *Industries* are implicitly accepted.

After all it seems to us that the ideal system is more probably to be found in *a combination* of the motor-generator and battery systems. Indeed, the advantages of this combination have by no means been overlooked by those engaged in the development of each type of apparatus. On this question we shall probably have something more to say before long.

The financial record of the Blackpool Electric Tramway Company reflects in miniature, but only too faithfully, the history of far too many a joint-stock enterprise. The remuneration of the Chairman, Managing Directors, Secretary and Manager—every one of whom is of course absolutely indispensable to the success of the enterprise—absorbs 38 per cent. of the total amount paid for wages. The company is therefore very naturally unable to afford the extravagance of a practical electrician to look after the insulation of the line. If the said insulation came to grief, and if electrical traction had in consequence to be abandoned for several weeks in the height of the season; and if, as a further result, there was no dividend to declare, are the Chairman, Managing Directors, Secretary and Manager to be blamed for these things?

While writing of the Blackpool Tramway, we may be permitted to take the opportunity of offering a word of congratulation to Messrs. Elwell-Parker, on the successful working of their motors upon this line. These machines have now been in use for a considerable period under conditions which have sometimes been of an exceptionally trying character, and have proved themselves thoroughly well adapted to the work.

The reason assigned by Mr. Esson (in our correspondence columns) for the slightly unequal sparking of the brushes in a two-pole dynamo, namely, that the number of lines of force passing through the half of the armature nearest the yoke-piece will be slightly in excess of the number in the other half, seems quite indisputable from a theoretical standpoint. Nevertheless, we happen to recollect that that fearful and wonderful apparatus, the Ball unipolar dynamo, did not perceptibly spark at one brush more than at the other, as it certainly seems it should have done. Of course we all know, on the other hand, that this machine never could and never would work according to any recognised theoretical assumptions.

Mr. Mordey's observations of the phenomenon of unequal sparking were made upon multipolar machines, to which Mr. Esson's explanation would not apply. The explanation offered by Mr. Mordey in another column is certainly very interesting, and we think that there is little room for doubt that an action of the character described is really set up, and that the phenomenon is adequately explained in this way.

The problem of the direct conversion of heat into electricity on an engineering scale is not yet despaired of by any means. We have now in our possession the details of a novel method, for which we are indebted to a well-known Continental electrician. We are not at present in a position to publish any account of this method, although we look forward to doing so before long. Meanwhile we may state that although we should hesitate to assert that a final solution has been arrived at, we have no hesitation in expressing the opinion that a distinct advance has been made, and that the inventor is working upon lines which may yet lead to results of the highest importance.

The sudden and almost unprecedented rise in the price of copper is causing some uneasiness among dynamo makers and telegraph constructors; but the best authorities on the subject seem to think that the rise is only temporary, and will be followed by a fall, perhaps quite as sudden, though not so great. It should be remembered that the price at the beginning of the present year was lower than it had been for ten years past. In 1877 the price was £76, in 1880 £72, and two years later £71, from which time it has steadily fallen. The mean price appears to have been reached in 1879, 1880, 1881, and 1884, when it ranged between £50 and £60.

Madrid.—Inquiries are being made in this city as to the substitution of electric for horse traction on the street tramways.

Torquay—Theatre Lighting.—An installation of electric light has just been carried out at the Torquay Theatre, under the direction of Mr. Radcliff. About 200 incandescent lamps have been fixed.

Societe Belge d'Electriciens.—We have received the fourth annual report of the "Société Belge d'Electriciens," containing a list of the general council and a report of the proceedings for the years 1886-87.

Mill Lighting.—Messrs. Greenwood and Co., of Rockville Corn Mills, Bacup, have just completed the fitting up of their extensive mills with electric light. The work has been executed by Mr. W. Bury, Manchester.

Digitized by Google

The Queensland Telegraph.—We are indebted to the Superintendent of Telegraphs of the Colony of Queensland for a copy of the "Report of the Post and Telegraph Department of Queensland for the year 1886."

The Atlantic Cables.—We have reason to believe that the statements of the *Central News*, published in *The Times* yesterday, relating to a threatened dissolution of the Atlantic Cable pool, are without foundation.

The Electric Light in the German Marine.—The German Lloyd Company of Bremerhaven have completed installations on twenty-two vessels, giving a total of 7,200 incandescent lamps and 44 dynamos. The machinery is furnished by the firm of Siemens and Co.

Obituary.—We regret to announce the death, at the age of 53 years, of M. Francis C. Guilleaume, which took place a few days ago at Maisenhausen. M. Guilleaume was a partner in the firm of Felten and Guilleaume, the well known wire manufacturers at Mülheim-on-Rhine.

Chatham.—The Chatham, Rochester and District Electric Lighting Company (whose offices are at 22, High-street, Chatham) are advertising for a steam engine to develop 150 indicated horse-power. We are glad to see that this local enterprise is showing signs of life.

The Glasgow Underground Railway.—Almost all the trains running between Airdrie, Hamilton, and Hyndland Station have now been fitted with electric light by means of Mr. Carswell's arrangement of a trailing conductor taking current from a central rail. The Glasgow and Helensburgh, Balloch and Milngavie services are also being provided with the appliance.

A Gas Company's Experience of Electric Lighting. — The Spencer (Massachusetts) Gas Company, who, as we recently mentioned, are running 60 arc lamps on a 6-ampere circuit, and are obtaining power from three Otto gas engines, find that, valuing their own gas at 50 cents per thousand cubic feet, the cost of fuel was at the rate of 0·75 cents per 1,200 candle-power arc lamp (nominal) per hour.

The Telephone in Italy.—The following are the statistics of the use of the telephone in Italy up to 31st October last:—

Venice	268 subscribers.	Turin	681 subscribers.
Naples	992 „	Genoa	409 „
Palermo ...	520 „	Florence ...	748 „
Catania ...	232 „	Bologna ...	375 „
Messina ...	183 „	Leghorn ...	388 „
Milan	1,213 „	Rome	1,835 „

A Century-Old Telegraph.—It is exactly one hundred years since Arthur Young made the first of his famous journeys through agricultural France; and Lady Verney reminds us in the current number of the *National Review* that on this occasion Young was introduced to "an ingenious mechanic," M. Lomond, who showed him "an electrical machine connected with a wire and a similar electrical meter at a distance where his wife writes down the words indicated by the motions of a pith ball—the length of the wire makes no difference."

Mr. Tomlinson's Experiments on the Thermo-Electric Properties of Iron.—In our report of the meeting of the Physical Society on Saturday week we inadvertently attributed to Mr. Tomlinson an observation for which Mr. de Tunzelmann was responsible. This was the suggestion that the results obtained by Mr. Tomlinson might very possibly be due to the total absence of strain in the molecular condition of the red-hot iron, while the cool wire must necessarily be in a state of more or less molecular strain owing to the contraction which takes place on cooling.

The Energy Expended in Electrical Traction.—From the experiments of M. Huber on the Ehrenfeld Tramway it appears that the storage batteries employed *receive a total charge* equal to 76 watt-hours per 1,000 kilogrammes carried 1 kilometre. This is equal to 123·8 watt-hours per ton-mile. On this line there is no gradient exceeding 2·5 per cent. M. Huber takes the efficiency of his dynamo at 80 per cent., and makes the work done by the engine equal to 95 watt-hours, or 0·13 horse-power-hour per ton-kilometre. This is equal to ·209 horse-power-hours per ton-mile.

Personal.—Mr. A. E. Kennelly, of the Eastern Telegraph Company, has accepted an appointment in Mr. Edison's laboratory at Menlo Park. Those who knew Mr. Kennelly best prophecy for him a brilliant career; but, while we congratulate him on entering so congenial a field of labour, we cannot help expressing our sincere regret at his expatriation. Prior to his departure for America a few of his many friends in the Eastern Telegraph Company presented Mr. Kennelly with a set of mathematical instruments and a handsomely bound set of Shakespeare's works, as a mark of their friendship and respect.

Electric Communication with Lightships.—At a meeting of the Dover Town Council on Wednesday last it was decided to forward a petition to the Queen, praying that immediate steps may be taken to establish electric communication between the Channel lightships and the shore. The recent disasters in the Channel were instanced as showing the urgent necessity of such communication, the "W. A. Sholten" disaster occurring within a very short distance of the Goodwin Sands Lightship. It was stated that Ramsgate, Margate, Deal, Sandwich and other coast towns had adopted similar memorials.

"**Fire!**"—A monthly journal bearing this startling title has just made its appearance, with the object of affording practical, scientific, and general information for the prevention of fire. It is published at 25, Bury-street, St. Mary-axe, E.C., and the price is one shilling. The first number, which has just reached us, contains a vast deal of useful information on the subject of fires and their causes, together with some well-considered original articles discussing the relative safety of the various systems of illumination now in use, including the electric light, and other kindred subjects of interest to insurers and insurance offices.

Finsbury Polytechnic and Working Lads' Institute.—We have been requested to state that Lord Wolseley will preside at the opening of the new Gymnasium and Social Room of the Finsbury Polytechnic, Appold-street, near Finsbury-square, on Monday, December 12, at 8:30 p.m. Since the swimming bath and temporary gymnasium were ready for use in January last nearly 400 members have been registered, and the institute is likely to prove as great a benefit to working lads of the East End as the Polytechnic in Regent-street is to those of the west. Its aims are to promote technical education and the physical and moral welfare of youths between the ages of 16 and 23. Tickets for the opening ceremony may be obtained of the secretary.

New York.—The Board of Electrical Control of New York City have adopted a standard design for lamp-posts that shall be hereafter erected by the electric light companies. The design contemplates a pole 20ft. high, exclusive of the lamp frame. For a distance of 7ft. from the surface of the ground the pole is to be of iron, and above this it will be of hard wood. This combination of materials is intended to prevent, as far as possible, all danger from shocks, as the wires carrying the cur-

Digitized by Google

rent will not be visible at any point on the iron pedestal. The post is of ornamental design, and as no part of the pattern is controlled by any patent, any company will be at liberty to erect the poles at first cost of material and labour.

The Electric Light in Hamburg.—The commission appointed by the Corporation of Hamburg to consider the question of undertaking the supply of electric light has presented a report recommending the establishment of a central station in the neighbourhood of Jungfernstieg, the management of which is to be entrusted to the town gasworks. The prospective cost of the undertaking is a million marks (£50,000). It is proposed that the consumers should pay at the rate of eight pfennigs (4·8d.) per ampere hour, the pressure on the mains being 180 volts. Besides this, an annual rental of five marks (5s.) will be levied on each incandescent lamp, double that amount being charged for an arc lamp. A reduction more or less considerable will be made in the case of large consumers.

Electric Lighting Notes from Spain.—A correspondent of *Industries* says that the largest independent electric light installation in Spain will be that of the Royal Italian Opera House, which is being carried out by the Schuckert Company. There will be about 1,500 glow lamps, and a dozen Krizik arcs. The town of Albacete, which has a population of about 20,000, and which has hitherto been lighted by oil, is adopting the electric light for private and public lighting, 16 candle power glow lamps being employed. The installation will be ready in a few weeks. The Municipality of Bilbao, which has some surplus engine power at their waterworks, intends to utilise it for lighting the principal thoroughfare of the town by means of thirty-two arc lights. Schuckert dynamos will be used.

An Electric Waiter.—The electric dining table in a restaurant at Sacramento is described as follows:—In the room are twelve tables, with a seating capacity for sixty persons, and all attached to the long electric motor table. Printed bills of fare are on each table, and visitors order by marking on the bill, placing the same on the waiter, which is about one-half the size of an ordinary waiter, and pressing the electric button, which causes the waiter to revolve half way around and into the long table, thence into the kitchen, where the order is filled and returned to the dining room. The arrangement is neat, noiseless, clean and comfortable, and to show with what smoothness the waiter does its work a brimming glassful of lemonade was ordered, and it was served without one drop being spilled. The table avoids all the many annoyances of restaurant dining, especially of the "sing-song waiter."

A Conference on Technical Education.—The following is a copy of a circular on this subject, issued from the Royal Victoria Hall Coffee Tavern, and which is referred to in our correspondence columns: — "Royal Victoria Hall, Waterloo Bridge-road. A public conference (non-political). A friendly meeting of employers and workmen to discuss technical education will be held on Wednesday, December 14th, at 8 o'clock; doors open at 7:15. Chairman, Sir Henry Doulton, supported by other influential gentlemen. Two short papers will be read, giving the two sides of the question, one by a working man, Mr. Bockett, and one by a man of science, Dr. J. A. Fleming, to be followed by a discussion. Anyone wishing to take part in it, please send name, address, and business to the hon. sec. at the hall. All seats free by tickets. Applications for tickets to be made of commissionaire at the stage door after Saturday next, 10th inst. Full band at 7:30."

An Electric Optical Lantern of 4,000 Candle-Power.—Messrs. Cox, Robinson and Co, of Liverpool, have constructed a lantern for optical experiments, combined with a Pilsen lamp, taking 26 amperes. The latter is so fixed that only a vertical movement is possible. This is effected by a rack, with very fine teeth, allowing the smallest adjustment to be made. The condenser and object glasses are mounted together on a stage, having three movements, so that the whole can be focussed in any direction to the arc. This combination admits of a perfect centring of the light, and answers remarkably well. The enormous amount of light allows almost any size of disc, and micro-objectives can be shown 60ft. in diameter. The above arrangement obviates many of the objections that have been made to electric lanterns, and when run from secondary cells, having a good margin of available current, the light is quite as steady as the lime light. This lantern was on view at the recent Exhibition at Liverpool.

A False Alarm.—Historical Note.—In the year 1795 it was greatly feared that nothing further in the science of electricity remained to be discovered. In 1795—before Faraday, before Ampère, before Œrsted, Davy or Volta! Prof. E. J. Houston has unearthed the record of this singular fact in a volume by one Siberius Cavallo, F.R.S., entitled "A Complete Treatise on Electricity in Theory and Practice, London, 1795." The passage referred to is quoted by Prof. Houston in a letter to the New York *Electrical World*, and runs as follows:—

"Since the time of this discovery, the prodigious number of electricians' experiments and new facts that have been daily produced from every corner of Europe and other parts of the world is almost incredible. Discoveries crowded (*sic*) upon discoveries, improvements upon improvements, and the science ever since that time went on with so rapid a course and is now spreading so amazingly fast, that it seems as if the subject would soon be exhausted and electricians arrive at the end of their researches. But, however, the *ne plus ultra* is, in all probability, as yet at a great distance, and the young electrician has a vast field before him highly deserving his attention, and promising future discoveries perhaps equally or more important than those already made.

Electrical Determination of the Mechanical Equivalent of Heat.—At a recent meeting of the Berlin Physical Society, Dr. Dieterici gave an account of his experiments on the determination of the mechanical equivalent of heat by the indirect electrical method. As the result of his series of measurements, he obtained closely agreeing values for the mechanical equivalent of heat—viz., 424·4 and 424·2 as the mean of each series; the highest and lowest values obtained differing but little from the mean of the determinations. When making his calculations, the speaker took as the specific heat of water the mean of the determinations made between 0deg. C. and 100deg. C. The statements which have been made respecting changes in the specific heat of water as dependent on changes of temperature vary so greatly with different observers, that the mean values based on their results do not provide any constant factor. The speaker's determinations would have been considerably different had he taken as his basis any other value of the specific heat of water. He next compared the results of his experiments with those of earlier observers, and discussed the very marked differences in the values given for the specific heat of water at various temperatures. He thinks that the specific heat of water may best be determined by the electrical measurement of the mechanical equivalent of heat, and intends to investigate this question more fully at a later date.

A Big Magnet.—A New York paper states that Major W. R. King, of the United States Engineer Corps, has recently constructed what is probably the largest electro-magnet ever made. The account proceeds:—"He has connected at the trunnions two 15in. Rodman guns, wound them with about four miles (ultimately he will use six miles) of old torpedo-

Digitized by Google

cable, and thus obtained, by the use of a thirty horse-power dynamo, an electro-magnet of enormous power. All the materials being already on hand, the means of really valuable experiments are thus provided almost without cost. The tests have not yet gone so far as to give quantitative results. In fact, only a preliminiary trial of the magnet (not yet fully wound) has been made, and its whole strength cannot be measured until it has been more firmly anchored. But it shows a tremendous power. One of the peculiar phenomena observed is that a 15in. shell, weighing 320 pounds, placed in the muzzle of one of the guns is violently forced out when the current passes through the wire; yet it does not leave the gun, but swings round to the lower side of the muzzle, where it remains hanging, like a carpet tack on an ordinary magnet, even with a second shell of equal weight depending from it. Twenty men cannot pull an iron rail from the muzzles of the guns while the current is passing. Major King has had an armature made of 11in. plates, built up to a thickness of 5 or 6in., so as to get a more suitable mass for the giant to work on, and a 5-ton Duckham dynamometer fails to register a force sufficient to remove it. We anticipate very interesting results from experiments with this magnet. Unless we are much mistaken, it will be by far the strongest in the world, weighing, as it does, more than 100,000 pounds."

A New Experiment in Magnetism.—The circular magnetisation which is developed in an iron wire while conveying an electric current has not hitherto afforded any direct experimental proof of its existence. Its effects in increasing the self-induction of the wire have been dealt with by Prof. Hughes, Lord Rayleigh, and others. We may also mention the proof afforded by Wiedemann's experiment on the longitudinal magnetisation of an iron wire conveying a current when submitted to torsion. But owing to the magnetic circuit being closed in the iron itself, direct experimental evidence of circular magnetisation was not forthcoming. A very simple and conclusive experiment has, however, been devised by M. Paul Janet, and formed the subject of a note recently presented to the French Academy by M. Mascart. M. Janet takes a cylinder of iron 30 centimetres in length by 1·5 centimetre in diameter, which has been cut longitudinally in halves and fitted together with great nicety. A current of from 30 to 50 amperes is passed through the cylinder for a few seconds. The two halves are then separated. A sheet of paper is placed upon one of the two plane sections, and dusting iron filings on this we find that, except near the ends, the filings arrange themselves in straight lines perpendicular to the two generating lines of the cylinder which form the longer sides of the rectangular boundary of the section. At the two extremities of the section the filings are arranged in curved lines, with their convex sides outwards. This shows clearly that the two generating lines are the *loci* of the poles of a series of semi-circular magnetic filaments, so that the whole cylinder must be built up of a series of annular magnets concentric with the axis, and magnetised with an intensity increasing with their distance from the centre, which is the distribution of magnetism indicated theoretically. A further verification may be obtained by suspending a magnetised needle parallel to one of the plain sections placed horizontally, when the needle will set itself perpendicular to the axis of the cylinder.

The Submarine Telegraph Company.—The *Central News* states that the negotiations between the French and English Governments for the joint working of the submarine cables have progressed so far that no doubt is now entertained that a satisfactory arrangement will be arrived at. After the return of M. Coulon, the French Postmaster-General, to Paris, the negotiations were continued by M. Waddington, the French Ambassador, and the provisional agreement arrived at has been taken by His Excellency to Paris for ratification by his Government. In the meantime, the directors of the Submarine Telegraph Company, who were despatched to Paris with a view to influencing the French Government in their behalf, have returned to London, and reported the failure of their mission. The French Government are so far committed to the proposals of the English Ministry that they distinctly decline to consider the question of any prolongation of the concession to the Submarine Telegraph Company. The English Government have been equally firm, the final resolution of the Cabinet just communicated to the Submarine Company setting forth that, having thoroughly examined the question, they have "decided not to grant a prolongation of the Company's license to land cables on British shores, and not to renew after the 12th of January, 1889, the working agreement between the Postmaster-General and the Submarine Company." The Post Office is desirous of dealing generously with the working staff of the Submarine Telegraph Company, recognising that it is a large and deserving one. As far as the cables are concerned the four which connect with France are in good order, recent repairs having made them almost as good as new. The two single cables to France now used by the American Telegraph Companies are also working very well. The two Belgian cables are in a fair condition. The telegraphic rate between England and France will when the final transfer is effected be reduced to twopence per word; but the special rate for press telegrams has not yet been fixed.

The Consolidated Electric Light Company of America.—The Consolidated Electric Light Company, owning the Sawyer-Man patents in America, has recently entered into several important engagements with other companies, which seem to portend a powerful combination against the Edison interest. The engagements are described as follows:—(1) It has granted to the Thomson-Houston Electric Company a license to manufacture and use incandescent electric lamps and attachments in plants and stations established by that company, in combination with its extensive and popular arc lighting system, upon an agreed royalty; and has also entered into a contract with that company whereby the interests of both companies, in the manufacture and sale of electrical apparatus other than that covered by the Sawyer-Man patents, are mutually promoted. (2) It has purchased from the Westinghouse Electric Company its valuable electric lamp factory and equipment at Pittsburgh, Pa., with a guaranteed capacity of 5,000 incandescent lamps per day; and has entered into an agreement with the Westinghouse Company whereby the purchasers from that company of its alternating apparatus for central station lighting shall also purchase from the Consolidated Electric Light Company the Sawyer-Man lamps and attachments for use with such apparatus, and shall have the protection of the Sawyer-Man patents. (3) It has purchased the stock and assumed the control of the Sawyer-Man Electric Company, which has heretofore been its sole exclusive licensee, and will conduct its commercial department through the agency of the Sawyer-Man Electric Company. It has purchased extensive manufacturing and business premises in the city of New York. To meet the increasing business demands of the Westinghouse Company, the Thomson-Houston Company, the Sawyer-Man Company and the general public, the Consolidated Electric Light Company will, within a short time, manufacture at its combined factories at least ten thousand electric lamps, with the necessary electrical attachments, per day.

SOME ENGLISH CENTRAL LIGHTING STATIONS.

I.—BRIGHTON.

In the autumn of the year 1881 Messrs. Hammond and Co. (since deceased) commenced to run at Brighton a small arc light installation, consisting of a sixteen-light Brush dynamo, driven by a twelve horse-power (nominal) Robey engine. From this small beginning the installation has steadily increased in importance until to-day it consists of five forty-light machines, supplying 34 arcs and over 1,500 incandescent lamps.

The station has from the first been under the sole charge of Mr. Arthur Wright, Electrician, and now also Managing Director of the local company. Mr. Wright, however, possesses far higher claims to distinction as an electrical engineer than have yet been named. He has devised and carried out, with the valuable help of Mr. G. F. Philpot, the under-electrician, and with unqualified success, an entirely unique system of constant current multiple-series distribution. For this purpose he has designed instruments and methods of working which are alike characterised by remarkable beauty and ingenuity, and by a practical and workmanlike construction which has enabled them to stand the test of prolonged and successful operation. These various apparatus and methods are for the most part in use nowhere else than in Brighton, and have never before been described in print.

There can be little doubt that prior to the introduction of transformers this installation constituted the most successful instance of long-distance distribution—not merely in this country, but anywhere in existence. With the advent of induction methods the high-tension direct current system has necessarily lost much of its general importance, but whatever may be its future the Brighton scheme will always possess considerable historical interest. It is scarcely necessary to observe that the great advantage of any practicable constant current system of distribution lies in the extreme flexibility of the method. This flexibility is apparent in two directions. In the first place any kind of arc or incandescent lamp, of any voltage and any candle-power, can be run on any part of the circuit; and, secondly, the question of the proportion of the mains, which so bristles with difficulty in the parallel system, is here entirely obviated, and a loop may be run out anywhere without any consideration for other parts of the circuit.

Seeing, then, that we have so much that is interesting to relate (without staying to give a connected history of the undertaking), we shall prefer to proceed at once to the system and appliances at present in operation, noting, however, the improvements which have been introduced from time to time in the details.

The Engine House.

The Brighton Electric Light Station is situated in Gloster-road, within a few hundred yards of the terminus of the L. B. and S. C. Railway. It is thus placed fairly in the middle of the town on the line from E. to W., though somewhat to the north of the exact centre. The engine house is a building measuring 70ft. by 55ft., and of good height. The facilities for shifting coal and ashes, &c., are excellent, and water is laid on from the town mains. Fig. 1 is an illustration of the exterior, taken from a photograph.

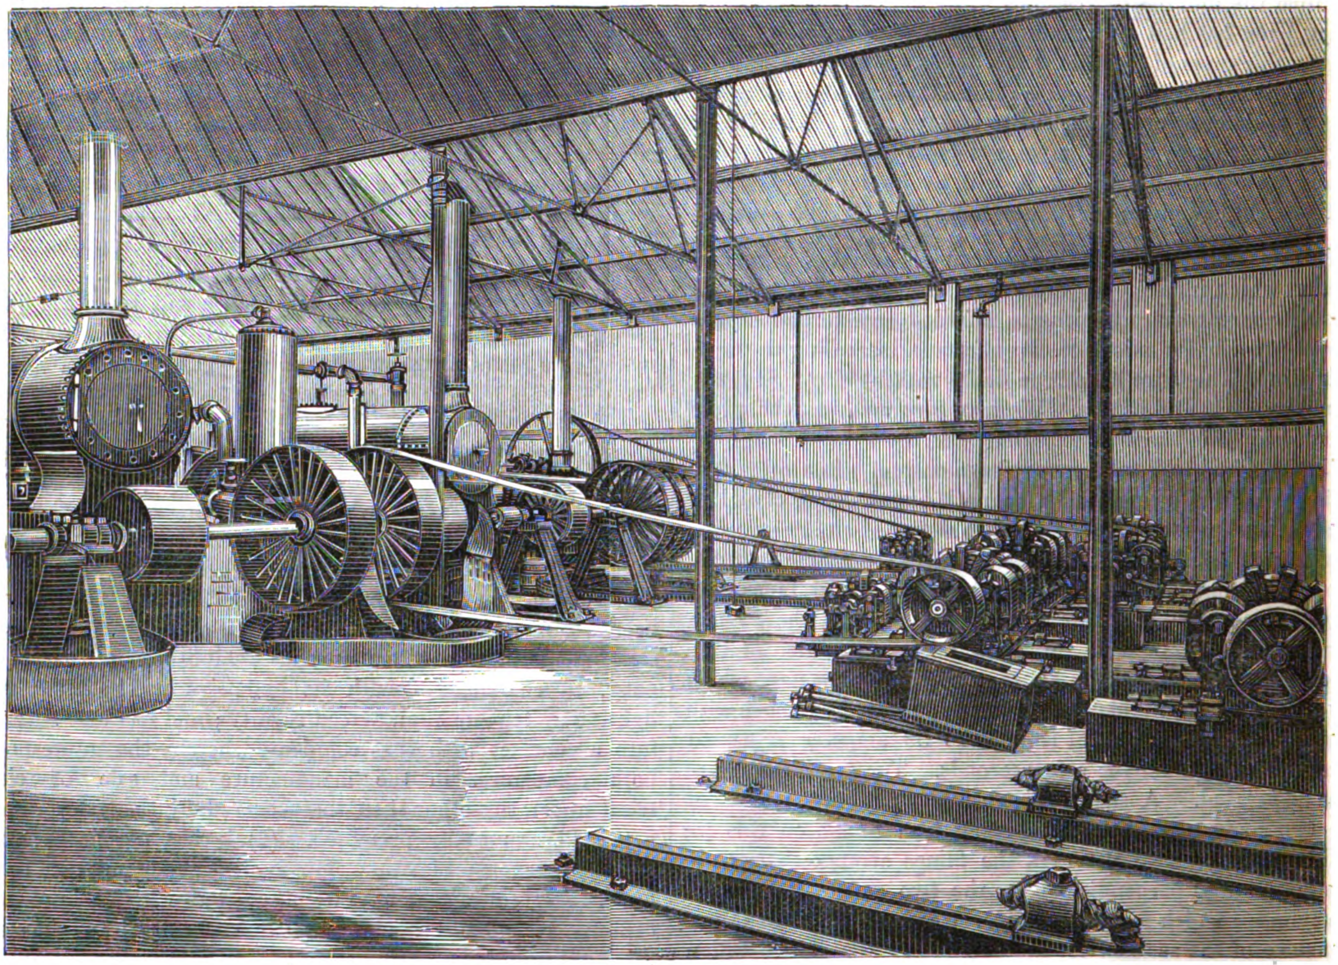

Fig. 1.

The Engines.

Motive power is furnished to the dynamos by two compound engines, each of 200 horse-power actual, by Fowler and Sons, of Leeds. These engines are of the semi-fixed type, with locomotive boilers over the cylinders. Mr. Wright speaks very highly of their performance, each engine being easily capable of developing four times its nominal power. There is also one smaller engine, by Hornsby and Sons, of 35 indicated horse-power, and of similar general description, used chiefly for the

Digitized by Google

day circuit. These three engines run at a maximum speed of 90 revolutions per minute, and drive on to the same countershaft by treble leather belting. There being plenty of space to spare in the shed the countershaft is on the floor level, the engines being in a row on one side and the dynamos on the other. The feed water passes through a Stanhope purifier, which reduces the hardness from 15 to 2 degrees. This apparatus costs very little for maintenance, and does its duty most effectually in saving the boilers from scale. The boilers are only washed out every three months, which is a very important consideration in a constantly running system.

The Dynamos.

There is nothing remarkable about the dynamos at Brighton except that, though continuing to do excellent service, they are of a type now considered obsolete. They are, in fact, early Brush machines with the "solid" armature. There are five machines of the 40-light type, giving 10·5 amperes and 1,800 volts at 900 revolutions, and one 16-lighter giving 800 volts, with the same current at the same speed.

The Method of Regulation.

As soon as it had been decided to make the experiment of running incandescent lamps in multiple series upon the arc

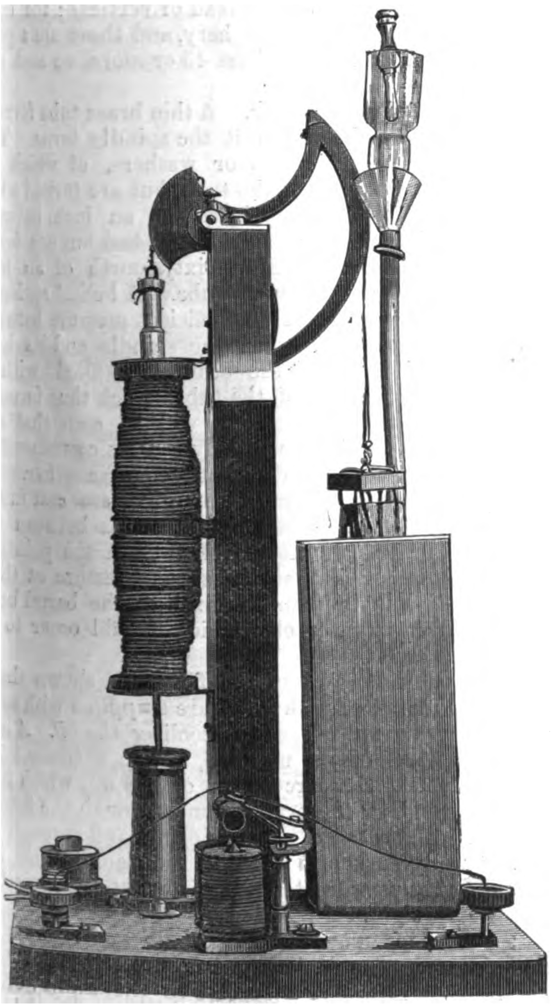

Fig. 2

light circuits (this was in 1883), Mr. Wright arrived at the conclusion—which his subsequent experience induces him strenuously to maintain—that for the economical working of central lighting stations it is essential that the speed of the engines should be varied in proportion to the output, in order to allow the engine to run as slowly as possible.

The method of regulation at first employed consisted in the use of a Brush pattern regulator in the form of a carbon resistance used as a shunt upon the field coils of the dynamos. The regulation was effected by hand, a boy being employed to watch an ammeter in the main circuit. This arrangement, though answering fairly well for arc lamps, proved unsatisfactory when incandescent lamps were placed on the circuit. Not only did the boy too often go to sleep, but the adjustment was neither sufficiently delicate nor as prompt as desirable, and the introduction of incandescent lamps as a portion of the resistance proved only a partial remedy. At the suggestion of Mr. Swinburne in October, 1884, a liquid resistance was substituted with considerable advantage; but the necessity for an automatic method of regulation become increasingly obvious.

The method by which this was eventually accomplished forms a unique feature in the Brighton system. So perfectly does the apparatus fulfil its purpose that the current is constantly maintained within 1 per cent. of the normal value.

Fig. 2 is an illustration taken from a photograph of the regulating apparatus. On the right-hand side is seen a vessel containing pure water, and through which a stream of water slowly trickles from the funnel seen in the upper part of the figure. In this vessel is suspended a pair of copper plates, between which is a platinum anode cut to the shape of inverted triangles, and hung point downwards, so that the liquid resistance between them varies rapidly as they are raised from or lowered into the vessel. These plates are connected with the terminals of the field coils, forming a shunt circuit. As will be seen in the figure, they are suspended from a form of sector which is pivoted on a standard at the back. A soft iron core hangs from the opposite side of the sector and descends into a solenoid. This solenoid is furnished with two windings, one upon the upper and the other upon the lower portion of the reel, but each so wound as to give a uniform magnetic pull throughout the length of the core's path. So far there is nothing especially novel in the arrangement; but now comes a very beautiful and highly characteristic device, which is intended to obviate the difficulty of "hunting," and which admirably fulfils its purpose. We are not at liberty fully to disclose the nature of the device in question (some portion of which can, however, be seen in the figure), but this much we may state: So long as the main current remains at its normal value momentary currents are sent through the two halves of the solenoid alternately; if, however, the main current should increase, then the successive momentary currents pass through the upper winding *more frequently* than through the lower, say, for instance, in the ratio of four to three; if the increase in the main current still continues this ratio also increases until perhaps it reaches two to one. The core therefore rises in the solenoid, the copper plates descend, and the field is weakened; the reverse action, of course, takes place when the main current tends to diminish. This highly ingenious arrangement effectually prevents any "hunting" tendency, and forms the most effective current regulator with which we are at present acquainted. The speed of the engines, which is regulated by hand, is, as already explained, always kept as low as possible, with a view to economy. It is therefore arranged that when the automatic regulator approaches the position in which the shunt on the field of the dynamo has the highest resistance—that is, when the electrodes are lifted nearly out of the bath—an electric bell is thrown into circuit, and the speed of the engine is then increased by the attendant. In a similar way a signal is given when the speed may be decreased. When several of the machines are working in series (which, as we shall more fully explain later, is the normal condition) it will easily be seen that it becomes necessary to arrange matters so that the signal to increase speed may be given by any one of the regulators; but, on the other hand, the signal for decreased speed must only be given when all the machines have mutually agreed to the alteration. This demand furnishes a very pretty little problem in circuit connections, and it has received a very complete solution in the present instance.

Ammeter.

While engaged in perfecting the regulator the necessity for obtaining a reliable ammeter was forced upon Mr. Wright's attention. On one occasion considerable trouble was experienced with the Brush lamps, and eventually this was traced to the fact that while the Ayrton and Perry ammeter in use continued to indicate the normal current, in reality the current

Digitized by Google

had fallen off in six months to little more than 7 amperes (!). The apparatus devised by Mr. Wright, and which has given perfect satisfaction, is seen in Fig. 3.

The scale of this particular instrument is so calibrated that at 10·5 amperes the index stands in the centre, and the closeness with which the regulation is effected may be judged from the fact that while the index moves continuously over a small arc on either side of the point, yet the extreme limit of the scale employed is only ·1 ampere from one side to the other.

Fig. 3.

This instrument is only a vertical solenoid which pulls down, more or less, a steel rod (always saturated) against a counterpoising weight.

(To be continued.)

THE CLARKE, CHAPMAN AND PARSONS TURBO-ELECTRIC GENERATOR.

In our report of one of Prof. Garnett's lectures on the electric lighting of the Newcastle Exhibition we mentioned that one of the chief features of the lecture consisted in the description of Messrs. Clarke, Chapman, Parsons and Co.'s turbo-electric generators employed in supplying current to the large incandescent lamps in the main courts of the Exhibition. A machine capable of giving an output of about 5 E.-H.-P. was exhibited complete on a small drawing room table, and one of the largest sizes of motors of the triple-expansion type was shown dissected, so as to exhibit the spindle and the interior of the barrel or cylinder with its rows of guide blades.

The accompanying figure represents one of the smaller sizes of turbo-electric generators, of which eighteen of different sizes were exhibited in the Exhibition, and the following detailed description of these remarkable machines will, no doubt, prove interesting :—

The steam pipe is attached at the flange immediately to the left of the pressure gauge. Below the pressure gauge is the throttle valve, controlled by the magnetic regulator. In the figure the barrel is shown of uniform diameter throughout its length, but in larger sizes the diameter is increased twice in passing from the centre to either end, practically converting the engine into a triple-expansion engine. The steam enters the barrel at the centre, passes through the succession of turbines to either end, whence it passes through a steam-way cast in the lower part of the barrel, and finally exhausts at the centre just below the admission port. The spindle is of steel, and carries a number of brass discs, reduced near the periphery, where the blades are cut to half the thickness they possess at the centre. The projecting ring thus formed has helical teeth cut upon it, constituting the moving blades, the pitch of the teeth varying along the length of the barrel to allow of the expansion of the steam. The discs are made of such diameter as just to turn freely with the spindle within the barrel, without risk of contact with the interior of the rings which carry the fixed blades. The spindle is made very stiff, so as to allow the clearance to be made exceedingly small, as it is found that the loss of power due to the friction of the spindle and its bearings is exceedingly small, and it is very desirable to prevent, as far as possible, the passage of steam between the barrel and the discs. Between each of these discs there is an annular wheel, with helical teeth, corresponding to those on the disc, but sloping in the other direction. These form the fixed or guide blades. The annular wheels are fitted closely within the barrel, the teeth projecting from one-half of their width only, and it is within the smooth cylindrical portions of these annular wheels that the moving blades or teeth of the discs actually turn. The barrel thus contains a double series of sirens very similar in principle to Helmholtz's double siren, only that the axis is horizontal instead of vertical; the holes in the discs are cut around the periphery, and there are a great number of pairs of discs, sometimes 45 or more, on each side of the centre.

The bearings are of great length. A thin brass tube forms a sleeve around the spindle, and in it the spindle turns. This tube is carried on a series of discs or washers, of which the alternate discs fit the outside of the tube, but are turned so as to allow a clearance of one-sixty-fourth of an inch between them and the bed, while the others fit the bed but are bored out so as to leave a clearance of one-sixty-fourth of an inch between their interior and the brass tube. A helical spring at the end of the bearing produces just sufficient pressure between the discs to carry the weight of the spindle and its load, while the last half inch of the bearing is filled with a washer bored out to the size of the tube, which thus forms a guide to keep the spindle true. It will be seen that any slight flexure of the spindle will only cause a corresponding transverse displacement of the discs between one another.

In the triple-expansion engines steam-ways are cast in the upper part of the barrel, making connections between the right and left portions of the barrel at both the points of enlargement. This equilibrates the steam pressure at these points, and prevents more than one-sixth of the barrel being thrown out of work if any obstruction should occur to the passage of the steam.

In the front, at the centre of the figure, is shown the oil vessel, the pipes connected with which are supplied with copper gills or radiators for the purpose of cooling the oil. A small screw on the spindle of the machine, at the extreme left of the figure, maintains the circulation of the oil, which flows continuously through all the bearings and through the interior of the armature. The rapid passage of the oil through the armature materially assists in keeping the temperature low, notwithstanding the very great electrical output of the machine in relation to its weight.

One of the most ingenious features of the generator is the magnetic governor. The field-magnet is shunt wound, but not nearly saturated. Hence any increase in the E.M.F. of the dynamo increases the magnetism of the field-magnet. Above the yoke is pivoted a bent iron bar, which is attached to a spring similar to the hair spring of a watch, so that this bar is mounted exactly like the balance wheel of a watch. Projecting from this iron bar at an angle of about 45deg. is a gunmetal fork, the extremities of which are formed with sharp edges and move immediately in front of the opening of the small copper tube which is seen in the upper part of the figure. This tube communicates with a circular bellows, shown above the left end of the barrel. The bellows are kept distended by a spring, but a small turbine on the spindle of the motor tends to exhaust the air and make the bellows collapse under the atmospheric pres-

Digitized by Google

sure. The throttle valve which regulates the steam supply is connected with the movable back of the bellows, the rod passing through a gland in the fixed front. When the iron bar above the field-magnet is inclined about 45deg. to the axis of the machine, the end of the copper tube is fully open, and air enters the bellows as fast as it is exhausted by the turbine, and the throttle valve remains fully open. If the E.M.F. increases, the iron bar turns in the direction of the lines of force against the constraint of the "hair spring," the end of the fork closes the air pipe, the bellows collapse under the exhaust of the little turbine, and the steam is shut off by the throttle valve. The action of this governor is so prompt, the moment of inertia of the moving parts of the machine being so small, that nearly all the load may be turned off the machine with scarcely a perceptible change in the brightness of the lamps remaining.

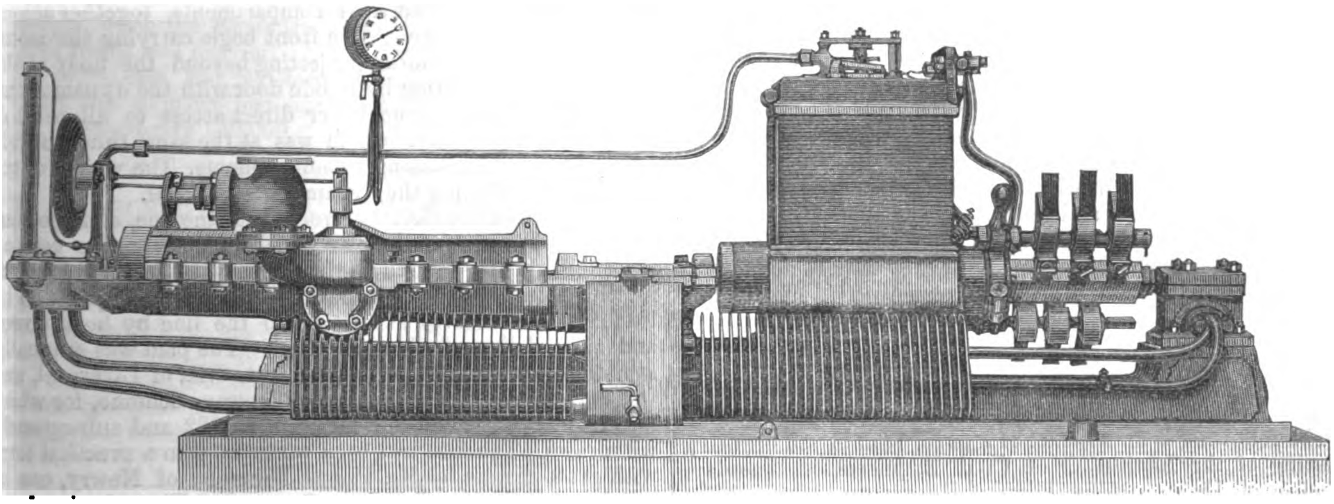
A common test of the governing arrangements of an electric light engine consists in suddenly breaking the conduction of the armature, so as to take off the whole of the load, and observing whether, under these circumstances, the engine runs away. If the connection between the armature and the field-magnet is broken, the latter of course loses its magnetism, and the magnetic governor swings back under the action of the spring only. The result of this is to bring the other prong of the fork in front of the opening of the air tube and by checking the influx of air to the bellows to cut off the steam supply.

It will be seen from the figure that the commutator is made of very great length. The brushes are of wire and press nearly "end on" to the commutator. The six brushes can be shifted into any position so as to keep the wear of the commutator even. The armature is of the cylinder type. The core is built up of thin charcoal iron plates, separated from each other by thin discs of paper. The discs are clamped up tight by two brass discs threaded on the shaft. The coils, which are laid in channels cut in the iron, are 30 or 40 in number, of stranded or solid copper wire, and each makes one complete turn. The whole is bound round with steel piano wire. The commutator segments are connected each to the ends of two adjacent coils, connected up in parallel. There are therefore 15 or 20 commutator bars.

The speed varies according to the size of the machine from 9,000 to about 10,000 revolutions per minute. The loss of power in the armature and field-magnet coils on the large machines amounts to only about one and a-half per cent., the high speed allowing exceedingly small resistance to be employed in the armature. A machine with an output of 32 electrical horse-power in the outer circuit is about 10ft. 6in. in length, and 1ft. 6in. in breadth. A small machine running a lamp of 1,000 candle-power, besides a number of smaller lamps, was exhibited in the Newcastle Exhibition, suspended by three wires. The exhaust pipe was of india rubber, and the steam pipe was provided with a flexible joint so that the machine could be shaken about while running. Properly suspended, such a machine would make a good gyroscope, and might be employed on ship-board, in connection with a Bessemer cabin, as well as for lighting purposes.

The oil is raised from the reservoir to the level of the screw propelled by the same turbine that exhausts the bellows of the governor. Exceedingly little oil is required. It is stated that in the smaller machines a pint of oil will last a fortnight. The E.M.F. of the machine can be regulated within moderate limits by adjusting the hair spring in the same way as the rate of a watch can be regulated.

From their extremely small size and weight relative to their output, and from the fact that the motion is one of pure rotation, with the parts perfectly balanced, and all the stresses, therefore, self-contained, it is obvious that these generators can be employed in many cases where ordinary engines and dynamos would be inadmissible. The locomotive, "Emigrant," built by Messrs. R. and W. Hawthorn, Leslie and Co., for the Midland Railway of Western Australia, was furnished with an incandescent search light, and was exhibited at the Newcastle Exhibition with a small turbo-electric generator in the cab.



THE CLARKE, CHAPMAN AND PARSONS TURBO-ELECTRIC GENERATOR.

ON THE UNEQUAL HEATING OF DYNAMO BRUSHES.

BY W. M. MORDEY.*

Probably many who have had an extended experience of the practical working of dynamos or motors may have frequently noticed that one brush shows a greater tendency in heat and spark than the other, or is more difficult to adjust to a non-sparking position than the other. The difference is generally very slight, and in good modern dynamos, in which the sparking has been reduced by well-known means to a negligible amount, it may be altogether imperceptible, except, perhaps, when an excessive current is being collected.

It has been supposed that this effect is caused by some inequality in the magnetic field, or that it has arisen from unequal pressure of the brushes against the commutator, or from some other mere matter of adjustment; but it appears to be something more than this. The view that an irregularity in the field is the cause of it is not borne out by its occurrence in the Victoria dynamos, for in them the cross-connecting of the armature, by bringing opposite portions of the winding into connection with one and the same brush, must have the effect of neutralising any such action.

The writer has sought in various directions for an explanation, and as he has reason to believe that the effect in question has frequently puzzled those who have observed it, and further, as it is believed that no explana-

* This Note has been in our hands for some three months, but has been withheld at the writer's request, in the hope that he might find an opportunity of obtaining further confirmation of the effect referred to. It has been thought well to give it now, the subject having recently been under discussion, as reported in our last issue.—Ed. E.

Digitized by Google

tion or notice of it has ever been published, he ventures to give his own view in the hope that he may either be supported by others or may elicit some more correct explanation. The difficulty is that the effect is so slight—it is, indeed, hardly ever of any practical importance—that it is only by a considerable amount of observation of a large number of dynamos that any reliable opinion can be formed as to its cause.

Neither an irregularity in the field, nor an irregularity of pressure of the brushes on the commutator, nor a variation of the shape and size of the brush surfaces is, in the writer's opinion, the explanation, although any of these may occasion an unequal amount of sparking much greater than that now being considered. The effect he believes to be due to a kind of electrolytic action—that is to say, to the action, whatever it may be, which causes matter to travel in the direction of the current, as exemplified, for instance, in the electric arc, in which the positive electrode is more quickly disintegrated and is heated more than the negative electrode

This view has received some support from observations of the action of dynamos and motors, in which it has been noticed that in dynamos the brush which is positive to the internal and negative to the external circuit is the seat of the slightly greater amount of sparking and heating, the reverse of this holding good of motors. A confirmation of this explanation has been supplied by a change of the sparking from one brush to the other when the polarity of the field-magnets of a dynamo—and therefore of the brushes—has been reversed, all the other conditions being maintained unaltered.

It may, perhaps, be objected that the electric arc effect should be equally present at both rubbing contacts; but it must be remembered that where the current passes from the commutator to the brush, the commutator, which is large and heavy, is constantly offering a fresh surface to the brush; whereas the brush, which is positive to the commutator, is comparatively small, and has its contact surface always in action.

It would be interesting to find whether any action of this kind has been noticed in what are called unipolar dynamos, as in them the generation and collection of current is a perfectly even and continuous process, unaffected by any of the disturbing effects which—however much they may be reduced—are inseparable from the principles of construction of ordinary dynamos.

THE BESSBROOK AND NEWRY TRAMWAY.

BY DR. E. HOPKINSON.

The following is an abstract of a paper read at the ordinary meeting of the Institution of Civil Engineers on Tuesday, the 6th of December, by Edward Hopkinson, M.A., D.Sc., A.M.I.C.E. :—

"Although a number of electrical tramways had been constructed in the United Kingdom during the last few years, there had hitherto been no attempt at the regular haulage of minerals and goods, nor at the operation of cars larger than the ordinary tramway type. Probably in no case had the effective power of any single motor exceeded about 4 horse-power. The principal object of the present paper was to describe the construction and to discuss the working of the Bessbrook and Newry Electrical Tramway, which had been designed for the haulage of heavy goods as well as for passenger traffic. The length of the line was rather more than three miles, with an average gradient of 1 in 86, the maximum gradient being 1 in 50. According to the conditions of the contract ten trains were to be run in each direction per day, providing for a daily traffic of 100 tons of minerals and goods, and capable of dealing with 200 tons in any single day, in addition to the passenger traffic. The electrical locomotive was to be capable of drawing a gross load of 18 tons on the up-journey, in addition to the tare of the car itself and its full complement of passengers, at an average speed of 6 miles per hour, and a load of 12 tons at an average speed of 9 miles per hour. Also, the cost of working, as ascertained by six months' trial, was not to exceed the cost of steam-traction on a similar line. The line was formally taken over by the company, as having fulfilled the conditions of the contract, in April, 1886, and had since been in regular daily operation. It was worked entirely by water-power, the generating station being adjacent to the line at a distance of about 1 mile from the Bessbrook Terminus. There were two generating dynamos of the Edison-Hopkinson type, driven by belting from the turbine shaft, which was extended into the dynamo shed for the purpose. The turbine could develop 62 horse-power, and each dynamo was intended for a normal output of 250 volts 72 amperes, though they were capable of giving a much larger output. The current was conveyed to the locomotive cars by a conductor of steel, rolled in the channel form, laid midway between the rails, and carried on wooden insulators nailed to alternate sleepers. The conductor was not secured, but was simply laid upon the insulators, which fitted into the channel, and while allowing for longitudinal motion to compensate for changes of temperature, held it laterally. At one point the line crossed the county road obliquely, the crossing being 150ft. in length. In this case the conductor on the ground level was not feasible, and an overhead conductor on Dr. John Hopkinson's system was substituted, by which the collector on the car consisted of a bar only, which passed under the supports of the overhead wire, and made a rubbing contact with its under surface. This system had been found to give very satisfactory results in practice.

"The locomotive equipment of the line consisted of two passenger cars, each provided with a motor. The body of the car was carried on two four-wheeled bogies, the motor being fixed on the front bogie, so as to be entirely independent of the body of the car. The longer of the two locomotive cars was 33ft. in length, and was divided into three compartments, the front one covering the motor, and the two others forming first and second class compartments, together accommodating 34 passengers. The front bogie carrying the motor had an extended platform, projecting beyond the body of the car, and communicating by a slide door with the dynamo compartment, thus giving the driver direct access to all parts of the driving machinery, which was at the same time entirely boxed off from the passenger compartments. The weight of the locomotive, including the dynamo, was 8½ tons.

"Apart from the electrical working of the line, an important and novel feature was the plan by which the waggons used on the line could also be used on the ordinary public roads, so avoiding the necessity of trans-shipment, and enabling goods to be loaded at the wharves and drawn to the line by horse-power and again delivered where required. The plan was originally suggested by Mr. Alfred Holt, M. Inst. C.E., of Liverpool, and was embodied in the Lancashire Plateways Scheme, for which a Bill was lodged in the autumn of 1882 and subsequently withdrawn. The idea had been worked out in a practical form with great success by Mr. Henry Bancroft, of Newry, one of the directors of the Tramway Company. The wheels of the waggons were constructed without flanges, with tyres 2¾in. wide, which was sufficient for use on ordinary roads. Outside the tramway rails, which weighed 41·25lb. per yard, second rails were laid, weighing 23·75lb. per yard, with the head ⅞in. below the head of the larger rails. The flangeless wheels ran upon these lower rails, the ordinary rails forming the inside guard. The front part of the waggon was supported on a fore-carriage, which could either be pinned or allowed freedom of motion as in an ordinary road vehicle. There was a single central coupling arranged to engage in a jaw on the fore-carriage, so as to guide it when not pinned. Shafts were attached to the fore-carriage when the waggon was to be used on the ordinary roads. The waggons were of sufficient strength to carry a load of 2 tons, and their weight without the shafts was 23¼cwt. Experience had shown that the wear and tear, both on the wheels and rails, was not excessive, and that the traction did not much exceed, if at all, that of ordinary trucks with flanged wheels. No difficulty had been found with the horse-traction on ordinary roads, and the taking on and off was conducted with great rapidity.

Each locomotive-car was fitted with an Edison-Hopkinson dynamo, which was geared by means of helical-toothed wheels, and a chain to one axle of the bogie. The special construction of driving chain, rendered necessary by the severe conditions under which it had to work, was fully described. The trains were commonly composed of one locomotive car and three or four trucks; but frequently a second

Digitized by Google

passenger car was coupled, or the number of trucks increased to six. Thus a gross load of 30 tons was constantly drawn at a speed of six or seven miles per hour, on a gradient of 1 in 50. The cars could be reversed by reversing the current through the motor without change of lead, but as there was a loop at each end of the line, reversal was only required when shunting in the sidings. The terminal loop-curves were of 55ft. radius only, but these were traversed by the long locomotive cars with perfect ease, to which the method of carrying the motor-dynamo on the bogie largely contributed.

The author concluded the paper with a discussion of an extended series of experiments to determine the efficiency of the whole combination under various conditions, and the distribution of the losses. The results were illustrated in a graphic form by a series of curves. Under average conditions of working the total electrical efficiency was shown to be 72·7 per cent., the losses being distributed thus :—

Loss in generator	8·6	per cent.
„ leakage	5·7	„
„ resistance of conductor	6·6	„
„ motor	7·7	„

The friction of the bearings in both generator and motor, and the power lost in the driving gear, were excluded from these results.

In an appendix to the paper the cost of the electrical equipment of the line was summarised, and the cost of haulage per train mile was shown to have been 3·3d. over one period of five months, when the goods traffic was light, and 4·2d. when the goods traffic was heavier. Since the opening of the line the locomotive cars had registered a train mileage of 40,000 miles, and the tonnage had exceeded 25,000 tons, and the number of passengers 180,000.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

With reference to the proposal to call a preliminary general meeting of electrical engineers for the purpose of discussing the new association, we are given to understand by those who have now the movement in hand that it has been found on inquiry among the leading firms of the metropolis that as no serious business could be undertaken between now and Christmas, the meeting will stand over till the turn of the year.

THE FAILURE OF THE BOILERS AT THE VIENNA OPERA.

On this subject the following additional information has reached us :—Six steel boilers, 120—140 horse-power each, were made for Messrs. Crompton and Company by the Witcourtz Iron Company in Moravia. Messrs. Crompton specified that the material used should be the best mild steel ordinarily used for boiler making. From the very first, however, the steel actually used began to give trouble; one of the plates in the water leg cracked under cold water pressure when it was tested, before steam was got up, and two other boilers failed within 48 hours of starting work. These defects admitted of temporary repairs ; meanwhile work was carried on with the other three boilers. After about twelve weeks' work, however, similar cracks began to show themselves in the main shell of the boilers, which were then considered dangerous, and the work was stopped by order of an Imperial Commission. The cracking is one of those instances which so often occur with steel boilers ; we may instance that of the Czar's yacht, the "Livadia," and which at the time excited great interest among the marine engineers. The cracks in nearly all cases appeared when the boilers were cooled down and opened up for cleaning purposes. The steel used was Bessemer, produced by the basic process. The whole of the six boilers were got out from the underground boiler house, and two large-sized locomotive boilers that happened to be available were got into position, and steam got up within nine days of the order to stop the defective boilers. The Opera was lighted on the tenth day. The whole of the rest of the machinery was found to be in perfect order, the accumulators not having suffered in the least. With the exception of this one failure of the boilers there has been no hitch whatever in the running of this large installation of 6,000 lights since the commencement.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

The general annual meeting of this society was held last night at the Institute of Civil Engineers, Great George-street, Westminster, when the undermentioned officers and council for the ensuing year were elected :—

OFFICERS AND COUNCIL FOR 1888.

President :
EDWARD GRAVES.

Vice-Presidents :

J. Hopkinson, F.R.S.	Prof. Ayrton, F.R.S.
William Crookes, F.R.S.	Alexander Siemens.

Members of Council Remaining in Office :

E. B. Bright.	H. R. Kempe.
R. E. Crompton.	Prof. A. W. Rücker, F.R.S.
Prof. J. A. Fleming.	Sir D. Salomons.
Prof. George Forbes, F.R S.	Augustus Stroh.

New Members of Council.

Capt. P. Cardew, R.E.	Gisbert Kapp.
Capt. Sir Douglas Galton, F.R.S.	Prof. Perry.

Associate Members of Council.

W. T. Goolden.	W. M. Mordey.	Major M. T. Sale, R E.

Honorary Treasurer :
Edward Graves.

Hon. Auditors :

J. W. Blundell.	F. C. Danvers.

Hon. Solicitors :
Messrs. Wilson, Bristowe, and Carpmael.

The report for 1887 was then read by the secretary, Sir Charles Bright presiding. It was announced that the Council had awarded the Society's prize of £10 to Mr. A. E. Kennelly for his paper on "Faults in Submarine Cables," the Paris prize and the Fahie prize of £5 each being assigned respectively to Mr. Sumpner and Mr. Fleetwood.

Mr. A. C. Cockburn, F.C.S., then read a paper on "Safety Fuses for Electric Light Circuits, and on the Fusing Points of Various Metals Employed in their Construction."

MEETINGS OF SCIENTIFIC SOCIETIES.
(Week ending Thursday, 15th December.)

SATURDAY, December 10th.

PHYSICAL SOCIETY (South Kensington, *3 p.m.*).
1. "Optical Properties of Phenyl-Thiocarbimide." By Mr. H. G. MADAN.
2. "Recalescence of Iron." By Mr. H. TOMLINSON.
3. "Rotation of a Copper Sphere and of Copper Wire Helices when Freely Suspended in a Magnetic Field." By Dr. H. C. SHETTLE.

MONDAY, December 12th.

SOCIETY OF ARTS.
8 p.m. Cantor Lecture.—Series I. "The Elements of Architectural Design." Third part. By Mr. H. H. STATHAM.

TUESDAY, December 13th.

INSTITUTION OF CIVIL ENGINEERS.
8 p.m. Discussion of Mr. Edwd. Hopkinson's Paper on Electrical Tramways.

WEDNESDAY, December 14th.

FINSBURY TECHNICAL COLLEGE.
7:30 p.m. Meeting of Old Students' Association.

SOCIETY OF ARTS.
8 p.m. Ordinary Meeting. "Commercial Education." By Sir PHILIP MAGNUS.

THURSDAY, December 15th.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.
8 p.m. *Conversazione* at the Institute of Painters in Oil Colours, 191, Piccadilly.

ROYAL SOCIETY.
4:30 p.m. Ordinary Meeting.

CHEMICAL SOCIETY.
8 p.m. Meeting.

*** Particulars of meetings to be held or papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial and Publishing Offices:
No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.
Telephone No. 2714.

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* THE PROPRIETORS.

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at Messrs. Smith and Sons' railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.*

The rates of subscription to "THE ELECTRICIAN" *(including postage) are as follows:—*

	3 months. s. d.	6 months. s. d.	12 months. s. d.
For the United Kingdom	4 11	9 9	19 6
,, Foreign Parts and Colonies:— Within Postal Union	5 6	11 0	22 0
,, Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	6 1	12 1	24 2

"The Electrician" in America.

"THE ELECTRICIAN" *can be obtained in America from* D. VAN NOSTRAND, *23, Murray-street, and 27, Warren-street, New York.*

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December, 1887.

All particulars relating to Advertisements will be at once forwarded, on application.

NOW READY.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

THE DISTRIBUTION OF POWER.

A report just published by the Municipality of Geneva on the utilisation of the motive power of the Rhone has attracted some attention in this country by the promise held out of solving one of the most difficult problems of modern industrial life. Switzerland is certainly a favoured land—favoured by the character of its people, by the goodwill of its neighbours, by its unique position in the family of nations, and last, but not least, by the bounty of Nature. The political institutions of this federal republic provoke neither envy nor apprehension; and the way in which she has turned to account her geographical advantages serves only to excite the wonder and admiration of Europe. Perhaps it would be well if she induced in us a greater spirit of emulation, for although we cannot transfer the swift-flowing Rhone to the bed of the Thames or the Mersey, any more than we can legislate by popular acclamation as they do in the Cantons, it is quite possible for us to copy in some degree the excellent example of the Geneva authorities in their solicitude for the welfare of the Swiss artisan. Their aims are set forth in the concluding portion of the report to which we have referred above:—"We believe," say the Municipality, "that we must endeavour to put cheap motive power within the reach of all, workmen as well as employers, if not as a complete remedy for the prevailing social crisis, at all events as a means of lessening its social dangers. For when power from a central source can be obtained in every house as easily as light and water are now obtained, one part at least of the problem will be solved by the workman becoming his own master."

The scheme which is being developed with this lofty purpose has already been at work for some years on a limited scale, and has proved thoroughly successful from a financial point of view. By combining their water supply with other requirements of the town, using for this purpose the inexhaustible power of the famous river on which Geneva stands, the Council have already found that they are able to pay not only the interest on the original outlay, but to cover the sinking fund. Possibly this fact may account for the high moral key in which the report is pitched. Municipalities which have hard work to make both ends meet do not usually add to their troubles by discussing social problems. Geneva, however, is exceptional apparently, not merely in its splendid natural resources, but in the enlightenment of its head men. But for their foresight, courage and wise direction the

Digitized by Google

utilisation of the water power of the Rhone on a greater scale, undertaken only a short time ago, would never have been attempted; and they are entitled to all the credit which they claim in the report now before us. Already by means of turbines and pumps the Rhone water is distributed, not only in Geneva, but to a considerable number of outlying communities. A great deal of this is used for the supply of mechanical energy in quantities varying from half horse-power to seventy horse-power, working no fewer than 175 motors within a radius of a mile and a quarter from the central station; and many of these motors are in the homes or workshops of the artisans themselves. It is this latter circumstance which affords the Municipality the greatest satisfaction, the report stating that the success of the scheme is due to the fact that the power has been carried to the worker instead of requiring him to come to the power, or, in other words, to aggregate the workers into a few large factories, with all the evil consequences, moral and physical, which attend the factory life.

Be this as it may the fresh extension of the works now proposed is the result of a rapidly increasing demand for the distribution of mechanical power; and the Council have under their consideration the expediency of introducing electrical transmission in conjunction with the hydraulic power hitherto employed. It is found that in the case of many workshops, chiefly of clock and watch makers, situated in the upper stories of buildings, there will be a saving by adopting electricity. We entertain no doubt that when once the electrical method is fairly at work it will in very many more instances than the Geneva Municipality seem to imagine prove superior in economy to the methods now employed. The Rhone is the most rapid river in Europe, and being swelled by a number of mountain streams just above the city, it offers a striking example of natural water power capable of being easily utilised. The idea of enlisting this mighty force in the service of electricity has arisen through the desire to illuminate the Geneva Theatre with the electric light. From this point of departure a further development is already contemplated; and a Municipality which has shown its business capacity in other directions is not likely to let slip the opportunity which such an installation will afford for extending its mechanical utility.

The question here naturally arises, could not something of the same kind be done for many of the industries of this country? We immediately think of what Spitalfields was and what Clerkenwell is. Scattered all over the United Kingdom are colonies of industrial communities, some of them quite as large as the area served by the Rhone turbines at Geneva; and it may be confidently predicted that many more would be created and grow apace if the requisite motive power at present chiefly concentrated in gigantic factories could be doled out to the operatives at their own homes. Here is a vision to gladden the heart of the social reformer, and could it be realised even to an extent that would stop a long way short of revolutionising the manufacturing industries of this country, it would go far to fulfil expectations such as those which are inspiring the Geneva Municipality in their praiseworthy efforts to ameliorate the condition of the working classes. We have no power-giving rivers to match the Rhone; but we have a far more abundant supply of fuel, and with this at our command a number of central stations for the distribution of electrical energy is by no means an outlandish suggestion, provided the users could be found in sufficient numbers to pay for the outlay. Electrical engineers are not expected to become philanthropists, and they cannot afford, like Municipalities, either at Geneva or Birmingham, to count on the exceeding great reward which the approving voice of Europe may bestow on them. But if in casting about them for fresh fields in which to employ the idle energies of electric lighting installations this one of the distribution of power were always kept in view, probably the search would not long be altogether barren. In America this has already been accomplished to an extent which is not accounted for by the differing circumstances of the two countries. Probably not a tenth of the number of motors which America can boast of have any existence in this country; yet America has introduced them without the least idea of solving any social problems, but on purely business principles. It seems to us that, though we cannot compete with the City Fathers of Geneva, we might emulate at least the electrical engineers of America.

A NOTE ON MOTOR-GENERATORS.

BY ALBION T. SNELL.

The increased demand for the distribution of electricity over large areas, and the evident inapplicability of a low tension parallel system to fulfil the commercial conditions of interest on the capital invested, has led to many ingenious modifications of the elementary system of distribution. At a first glance it is seen that any method to be successful must, broadly speaking, comprise a high tension distribution in the mains and a low tension one in the submains.

As one would expect, the earliest attempts to solve this problem were made with alternating currents. The general properties of alternating currents have been understood for some time, and induced or secondary currents have been utilised for various purposes. The alternating transformer is in fact a development of the Ruhmkorff coil. There is something very fascinating about such transformers, both to the engineer and to the scientist. The absence of moving parts, the simplicity of construction, and the closed magnetic circuit, with the consequent high magnetic induction, are all in favour of this interesting converter of energy—we cannot say machine. There are, of course, certain drawbacks even in these, apparently, simplest of converters. Alternating transformers, although approximately self-regulating when coupled in parallel, are very uncanny things when in series, and as yet they do not seem to have met with much success when supplied with constant current. And, moreover, since the secondary circuit has an alternating current they cannot be used directly for charging accumulators, nor without special precautions for running electric motors, as now designed. These two obstacles are, perhaps, not insurmountable. Alternating currents can be commutated, it is well known, but there seems to be no really commercial method of doing this at present. No doubt, when there is sufficient demand, the problem will be solved in a satisfactory way. Alternating motors, too, which are both self-starting and independent of the phase of the current are not by any means impossible.

But another method of solving the distribution of electricity, without abandoning the use of continuous currents, has lately attracted much attention.

Before criticising these continuous current transformers, or motor-generators as they are more briefly called, it will be well to refer to them by name. During the last few weeks articles have appeared in the columns of this journal on the "Paris and Scott Motor-Generator," the "Edison System of Continuous Current Transformers," and, more recently, on the "Jehl and Rupp Transformer," which is also continuous.

The Paris and Scott motor generator is really a motor with two windings on the armature, each winding having its own commutator and brushes. The field is excited by a shunt from the secondary or dynamo part of the armature. Since the object aimed at is constant potential on the secondary terminals, we may assume the field to be excited by a constant current, and therefore, neglecting the disturbing influences of

Digitized by Google

the armature, a constant number of lines of force is supplied to the circuit. The variables then are the currents in both the primary and the secondary circuits, and if the E.M.F. of supply be constant it would appear that the desired condition of constant E.M.F. at the secondary terminals with varying load is obtained. That this is practically so the writer knows from experience, having had the opportunity of testing the machine at the Newcastle Exhibition.

And it is probable that a number of these transformers in parallel, supplied at constant potential, would give very satisfactory results. But when supplied with constant current the difficulties are increased. Assuming the machine to be constructed as now, and the field to be constant, the primary E.M.F. would have to vary directly as the secondary current. This would appear to be impossible. The strength of the field must be varied as in a constant current dynamo. The difficulties to be met with here are well known, and need not be discussed. Suffice it to say the machine lends itself to a constant potential distribution, but, as far as the writer sees, requires considerable modification before it would be adapted for working a constant current circuit.

The Edison system differs essentially from the Paris and Scott in the respect that only the commutator revolves, and the armature coils are coupled direct to stationary brushes. There is an apparent simplification in thus keeping the armature and brushes at rest; but since an independent source of power has to be found for rotating the commutator, the gain seems doubtful. It is not necessary to refer to the structural details of these transformers, which are already familiar to your readers. It will only be necessary to say that all the difficulties pointed out in the Paris and Scott transformer are also found here. They will give constant potential with varying load if supplied at constant E.M.F.; but a self-regulating series system is as far off as ever. In fact, such a transformer requires an automatic governor for varying the number of lines of force generated in each coil in direct proportion to the load. This is a very pretty problem. Edison has also a "rotation transformer." In this the armature has two separate sets of windings, commutators and brushes. The whole is surrounded by a stationary ring of laminated iron, which serves to lower the magnetic resistance and concentrate the field. The weakest part of this arrangement is that it requires to be driven by an independent motor.

The Jehl and Rupp system shows much originality, and is evidently the outcome of a good deal of experimental work. Several types of alternating and continuous transformers are described, but it is only intended here to refer to the latest motor generators. These transformers are broadly divided into two classes, one for parallel distribution, the other for series. It is worthy of note that this is perhaps the first successful attempt to run constant current transformers. In all the latest types the motor generator itself is stationary, and the commutator only is rotated. This resembles the Edison system so far. The chief difference is found in the arrrangement of the coils. Both wind the primary and secondary circuits on separate cores; but Edison further subdivides the several coils of each circuit on different cores, while Jehl and Rupp are content with one core for the primary and one for the secondary. Since the theoretical conditions are identical, the better plan can only be decided by time, the questions of cost of production and efficiency of running being the most important factors.

The distribution commutator is somewhat complicated, but care has evidently been taken to reduce to a minimum the risks of breakdowns. And here, again, comes one of the weak points of motor-generators—the motor to rotate the commutator. Of course the motor has very little work to do; but yet another link is added to the already long chain. A parallel distribution by this means would be self-regulating if the resistance of the secondary circuit was sufficiently low. Only one distribution commutator is necessary for each centre or group of transformers, for all the rings are coupled to the same distributor, there being as many wires from each as there are coils.

Jehl and Rupp have also another practical form adapted for constant potential circuits in which the distributer is not used. In this the primary and secondary circuits are wound on separate iron cores, the one a ring and the other a drum. The ring is fitted securely outside of the drum, and the whole is surrounded by a laminated iron ring. The windings are coupled to separate collectors on a shaft passing through the centre of the drum. The brushes are stationary. The whole machine is rotated by a motor. Since the brushes alone are at rest, it follows that the axis of magnetism will remain fixed with reference to space if we neglect the vibrations due to the reversals of current in the coils immediately in contact with the brushes. The position of the brushes is a matter of no importance, and there should be no sparking. The transformer would regulate if supplied at constant potential, if the speed of rotation did not vary and the internal resistance were low. If a motor generator of this type were supplied at constant current, and were rotated by an ordinary series-wound motor, it would not give constant potential on the secondary terminals. For running in series Jehl and Rupp provide another form of the apparatus. This type is remarkable, as it only has one winding. In its simplest form a Gramme ring is surrounded by a laminated iron ring, and is mounted on a shaft carrying a collector. The whole is rotated by a motor driven by the main current. The brushes are stationary. The lamp circuit is a shunt to the transformer terminals. If the lamp circuit be open the whole of the main current will pass through the motor-generator. When it is closed the current divides between the two circuits in proportion to the resistances. The lamp circuit will take maximum current when the motor-generator is running at its greatest speed. The regulation for constant potential on the terminals can thus be secured by varying the speed of the driving motor. This is done by means of an electrical governor, which varies a shunt to the series-motor in the main circuit. Another method practised by the inventors is to put a variable shunt to the lamp terminals. The desideratum of regulation is simply that the back E.M.F. equals the potential required for the lamp service plus the number of volts lost over the internal resistance of the transformer.

In another form of these series motor-generators the commutator only revolves, as in the constant potential types. The method of supply and regulation is the same as in the other. The disadvantage, other than the independent driving motor and the moving part, is that the energy absorbed appears to be practically the same whether the transformer is running light or with full load. This is a very serious drawback, and, if correct, will prohibit the extensive use of the apparatus. The writer believes this to be the only attempt at running continuous current transformers in series. That the object sought is obtained there appears to be no doubt, though the multiplicity of parts and the constant rate at which energy is consumed for a variable useful effect do much to militate against the system. MM. Jehl and Rupp, however, are to be congratulated on their present success, but no doubt some less complex method of solving the problem will follow shortly.

Reviewing, then, what has been accomplished with continuous current generators, and bearing in mind the object of this inquiry, the applicability of such machines to a method of general distribution, the writer does not feel that the problem is much nearer solution. It will be noted that, with one exception, these transformers do not readily lend themselves to a constant current distribution, and the exception has a poor commercial efficiency if the output demanded be a variable one. Again, all of these systems have moving parts, and two require independent motors for rotating a portion or the whole of the apparatus. This is an objection which only becomes serious when it is proposed to employ the apparatus under circumstances where little or no skilled attention can be given; but, generally speaking, that system which has the fewest moving parts is the most likely to give the best average results, and the more so when it is borne in mind that the risks of breakdowns from defective or damaged insulation must always be greater with moving than stationary coils. More attention, at any rate, is likely to be entailed by these transformers than with alternating ones, which have no moving parts.

The strong point of the motor-generator is the direct secon-

Digitized by Google

dary current. It can be used for charging accumulators, and for driving ordinary motors. This alone is enough to ensure a large field of usefulness for the apparatus. Another important difference between the two types is found in the efficiency of conversion. From the very nature of things the motor-generator cannot be so efficient as the alternating generator. From the data already existing, the efficiency of an alternating transformer averages about 95 per cent.; the Paris and Scott motor-generator, judged by the Newcastle tests, only gives a return of about 86 per cent. A difference of 9 per cent., although, perhaps, a small matter in an isolated installation, must be a very important one in a system of general distribution.

The conclusion may be roughly stated thus:—Continuous and alternating transformers are equally adapted for parallel distribution, and they both, perhaps, are on much the same footing as regards a series system. Alternating transformers are superior in the respect that they have no moving parts, and have a higher efficiency of conversion. Motor-generators have the advantage of giving a direct current in the secondary circuits. How long this apparent balance will be maintained is a matter of speculation. It may, however, be taken as an axiom that either system, to come into general use, must have a high tension (probably a series) primary distribution and a parallel secondary.

ON SOME INSTRUMENTS FOR THE MEASUREMENT OF ELECTROMOTIVE FORCE AND ELECTRICAL POWER.*

By J. A. Fleming, M.A., D.Sc., and C. H. Gimingham.

These instruments do not present any novelty of principle. They differ from that form of instrument generally called an electro-dynamometer in the arrangement of details, but they

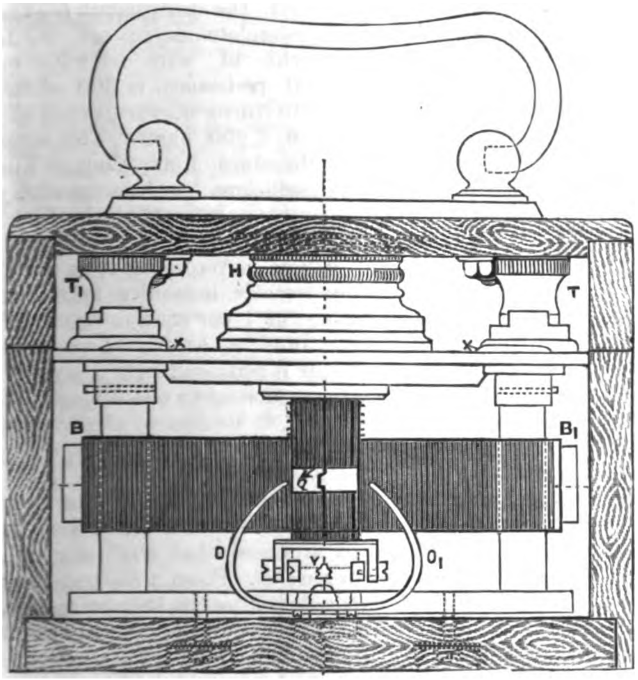

Fig. 1.

depend for their operation upon the electro-dynamic action of currents in fixed and movable conductors. Our object has been to furnish an electro-dynamometer which shall be portable, compact, and require in its use no mercury cups, tables of square roots, nor multiplying factor, nor any reference other than to the scale of the instrument, in order that electromotive force and power may be determined by it at once. Our experience in the use and testing of voltmeters of nearly every kind has been such as to lead us to look doubtfully at any instrument which either contains soft iron, permanent or electro magnets, or in any way depends for its action on the behaviour of iron when placed in varying or successively varied magnetic fields. No matter how treated, a piece of soft iron has a "magnetic memory." Unless rapid magnetic reversals, aided by rise of temperature, are brought to bear upon it, it is very difficult to eliminate from it the results of its previous magnetic history and to bring it back into the condition in which its magnetisation is the result, purely and simply, of the present magnetic force brought to bear on it.

* A paper read before the Society of Telegraph-Engineers and Electricians, November 25th, 1887.

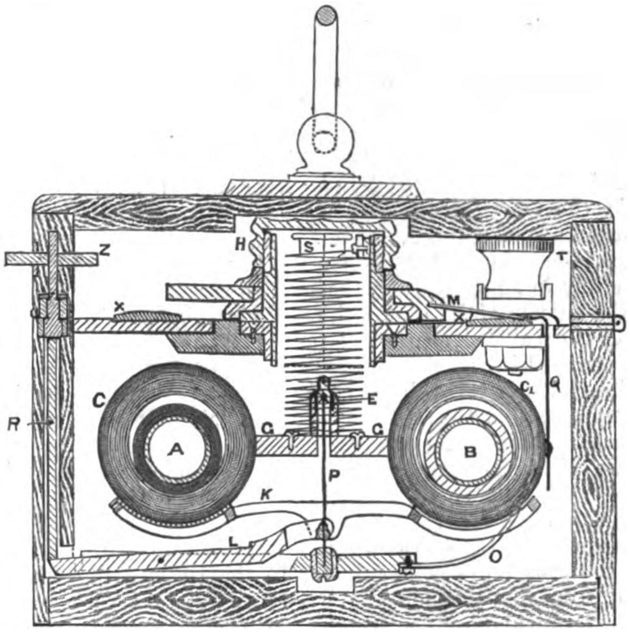

Fig. 2.

We start, therefore, with the principle now adopted by Sir W. Thomson, that in thoroughly satisfactory electric-measuring instruments the magnetisation of iron must not be permitted to play any part in the design. In these instruments we submit to

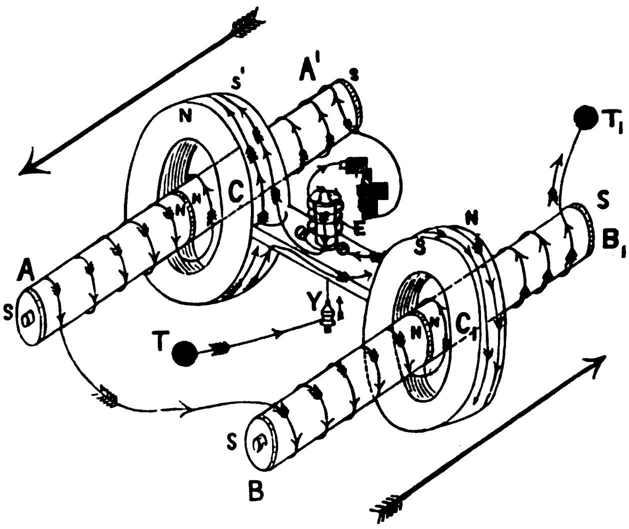

Fig. 3.

the criticism of the society the action is wholly based on the fact that when conductors conveying electric currents are arranged so that one of them is fixed and the other free to move, the force required to hold the movable conductor in any given position in the field of the fixed conductor is proportional to the product of the strengths of the current flowing in these conductors respectively. The general arrangement of the high resistance dynamometer or voltmeter is shown in Figs. 1 and 2, which show cross sections of the voltmeter. The general design of the instrument is as follows:—A A^1

Digitized by Google

B B[1] (Fig. 3) are two solenoids of insulated wire (German silver) wound on brass tubes. The solenoids are wound so as to have a magnetic pole in the centre of each, marked N N. The ends of the solenoids are therefore similar poles, S. Two such solenoids are held in a frame, and fixed so as to be parallel to each other. The general arrangement of the voltmeter free from detail is shown in Fig. 3.

These fixed coils are embraced by two annular coils, C C[1], which are wound on exceedingly light metal frames, and are carried on the ends of an ivory bar, G G (Fig. 2). The resistance of the fixed coils may be about 1,000 to 1,500 ohms, and the resistance of the annular coils about 500 to 1,000 ohms. This ivory bar carries at its centre a glass-hard steel cup, by which it is supported, so as to move freely, like a compass needle, on a steel iridium-tipped needle, P. The coils are very accurately balanced, and, whilst embracing the fixed coils, have yet clearance enough to permit them to swing through a small angle on either side. Their range of movement is, however, limited by two stops, O O[1] (Fig. 1).

To the ivory cross bar carrying these movable coils is attached a steel spiral chronometer spring, the upper end of which is held in a tubular collar, H (Fig. 1), capable of revolving stiffly in an aperture in the dial plate. This collar carries on the outside of it a mica-tipped index finger. The index finger is capable of being set round on the tubular collar H, and clamped in any position.

The inside of this tubular collar has an attachment by which the upper end of the steel spring can be taken up more or less, just as the hair-spring of a watch is set.

The electrical connections of the voltmeter are shown in Fig. 3. It will be seen that the current enters from one terminal, T[1], passes thence to the top of the spring, then down the spring into the movable coils C C[1], from there to the steel cup E, through the contact point to the iridium-tipped steel pivot, from that through the fixed coils and so back to the other terminal T. The windings of the movable coil are so arranged that it is astatic, and not influenced by a vertical or horizontal uniform field. This is important in an instrument to be used in the neighbourhood of powerful magnets.

The movable coils carry a light aluminium needle Q which projects up through a slit in the dial plate, opposite to the zero of the scale.

The whole instrument is contained in a small wooden box, about 4½in. square by 3in. deep. On opening the box a dial plate is seen having a circular scale divided so that the volt readings are obtained without any calculations. The operation of taking a reading is as follows:—The box is first levelled on the table by means of a wooden wedge provided for the purpose. The central hollow boss is first turned until the mica index finger is at the zero of the scale. The aluminium index, carried by the movable coils which project up through a slit in the dial, should also be opposite the zero. If this is not the case the mica index finger has to be shifted. This is accomplished by slacking up the milled head on the top of the central boss and readjusting the index until the mica index finger and the aluminium index of the movable coils both stand opposite to each other at the zero. The current is now passed, and the electromagnetic action causes the movable annular coils to be shifted along the fixed coils, displacing the aluminium index. The central boss, carrying the upper end of the spring, is then turned until a torsional force is brought to bear on the movable coils, bringing them back against the electromagnetic forces into the zero position. It will now be found that the upper end of the spring will have been twisted through a certain angle, as indicated by the position of the mica index finger. The value of the current passing through the instrument is proportional to the square root of this twist required to bring back the coils into their zero position, and, as the force brought to bear on the coils is proportional to the angular displacement of the upper end of the spring, it follows that the square root of the angular displacement of the mica index finger required to maintain the movable coils at their zero position is proportional to the strength of the current flowing through the instrument. To avoid any calculations or reference to square-root tables, the dial is graduated in the following manner:—If the instrument is intended to read, say, from 20 to 110 volts, then one complete turn, or 360deg. displacement of the index, is required to balance the electro-magnetic force due to 110 volts on the terminals of the instrument. The angular displacement for x volts is, then, $\frac{360 \times x^2}{(110)^2} = \frac{18}{605} \times x^2$, measured in degrees, and accordingly the positions for all volt values from 20 to 110 can be set off directly on the dial. The index needle is then simply turned until the aluminium index is brought back to zero, and the dial reading gives at once the volts. This form of graduation has the advantage that the scale interval corresponding to one volt is greatest in that part of the scale which will be in each instrument presumably most used.

In order to render the instrument portable, means are provided to raise the movable coils off the point P (Fig. 2) by the action of closing the box. A clutch-bar, K, is so arranged and pivoted that by means of a pin, R, sliding in a hole in the box a pressure on the upper end of this pin raises the coils, C C[1], and relieves the iridium point of the pressure of the movable coil-bar.

It is not desirable that the movable coils should be taken up and let down suddenly on the pivot, and to make this action deliberate the box lid is opened and closed by a screw. The user is thereby compelled to open the box slowly and let down the coils with a gentle motion on to the pivot P.

The voltmeters are constructed to work over various ranges. One type ranges from 20 to 110 volts. By associating a resistance coil with the voltmeter, the resistance of which is equal to that of the voltmeter, the volt values of all the readings become doubled and the instrument becomes available for use between 40 and 220 volts. In order to give a little margin over and above the 110 and 220 volts, the graduation is continued, according to the square-root law, along an outer circle. A little more than one complete twist of the spring enables a reading to be taken up to 115 or 120 volts on the 110-volt instrument, or to 230 or 240 on the 220-volt instrument. In the 110-volt instrument (construction A), the following are the electrical and mechanical data of the instrument:—The weight of the movable coils complete is in all 20·27 grammes. The number of turns of wire is 960 on both coils together, and the total resistance is 300 ohms. The four fixed coils have each 840 turns of wire, or 3,360 turns in all, and a resistance of 1,200 ohms. The total resistance of the voltmeter is therefore 1,500 ohms. The temperature resistance variation coefficient has been carefully determined for a mean temperature between 15deg. and 30deg. C. for the particular kind of German silver wire used, and it is ·0273 per cent. per degree. Accordingly, as far as regards change of temperature as a whole, it requires an alteration of 30deg. C. to make a change of 1 per cent. in the value of the voltmeter readings. To prevent, as far as possible, heating of the coils, each voltmeter is provided with a key. In using the instrument the first operation after opening should be to level it carefully, by inserting, if necessary, the wooden wedge provided under the front or back side until the pointer on the movable coils swings freely from side to side.

We have also constructed, on this type, a wattmeter. In this case the fixed coils (now called the current coils) are wound with thick wire, and so arranged that the four coils can be joined up in series or in parallel. From a separate pair of terminals the current is conducted into the thin wire coils, which are the movable coils, and constructed exactly as for the voltmeter, only with a higher resistance. In using this wattmeter for measuring the power taken up, say, in an incandescent lamp, the lamp should, as usual, be put in series with the thick wire coils R. The fine wire coils r should have their terminals joined, not to the two terminals of the lamp, but to the terminals of the lamp and the thick wire coil as joined in series. The thin wire coil thus measures the potential at the extremities, not of the lamp, but of the lamp and thick wire coil in series. The reason for this is as follows:—Suppose the thick wire coil to have a resistance of ·01 ohm and the thin wire coil to have a resistance of 1,000 ohms, and apply this wattmeter to measure the power consumed in two lamps, each of 8 candle-power and requiring, say, 20 watts—but in one case let the lamp be a 100-volt lamp taking ·2 ampere, and in

Digitized by Google

the other a 10-volt lamp taking 2 amperes. If the fine wire coil is joined in parallel with the lamp alone, in the case of the high-volt lamp, since the resistance is 500 ohms hot, the lamp will take two-thirds of the whole current flowing through the thick coil—in other words, the current which flows through the thick coil is not that flowing through the lamp, but that through the combined resistance of lamp and fine wire coil. If, however, the same wattmeter is applied to measure the power of the low-volt lamp, then, since the hot resistance of this is only five ohms, the lamps will get $\frac{1000}{1005}$ths of the current flowing through the thick coil. It follows from this that whereas the two lamps consume exactly the same power, yet, in the first case the current in the thick coils, which is that which actuates and is one of the factors in determining the reading of the wattmeter, is half as great again as it should be. It would be found that in the case of the high-volt lamp the wattmeter reading would be 30 watts, and in the case of the low-volt lamp 20 watts, although both lamps actually take the same power. If, however, the extremities of the voltmeter, or movable or fine wire coils, are joined, as shown in the figure above, then the current in the thick coil is exactly that through the lamp, the error in the electromotive force part of the measurement is then only dependent on the fact that the thick wire coil has an appreciable resistance; if this is only ·01 ohm, the error made in the electromotive force part of the measurement is only ·1 per cent., even in the case of the low-volt lamp, by assuming the potential at the extremities of the lamp and thick coil in series as equal to that at the terminals of the lamp.

Unless the resistance of the current coils is vanishingly small compared with that of the high resistance or movable coils, the above method of joining up the wattmeter does not give the real rate of dissipation of energy in the lamp or other circuit under consideration.

(To be continued.)

DISCUSSION ON MEASURING INSTRUMENTS AT THE SOCIETY OF TELEGRAPH-ENGINEERS

At an adjourned meeting of this society on Thursday evening, December 1st, the discussion on the papers read by Dr. Fleming and Mr. Gimingham and Profs. Ayrton and Perry was resumed. Sir Charles Bright presided, and there was again a good attendance of members.

Mr. ALEXANDER SIEMENS said he was very glad to have had the opportunity of hearing Prof. Fleming's paper, and to see the new form of dynamometer which had been elaborated from the original design of the instrument as made by his firm. He had brought an instrument there which was the latest form in which their own dynamometers were constructed. In using it they employed mercury cups, and they worked perfectly well. The new type was designed especially for use on ship board, where the ordinary type was not very serviceable, and, moreover, it had the great advantage of being direct reading, the indications being proportionate directly to the current. This instrument was due to Mr. Raworth, by whom it was designed at the time when he was in their (Messrs. Siemens) employ. It had no movable contacts, which was an advantage not possessed by Dr. Fleming's instrument. He had the actual instrument there, and would explain the principle. Dr. Fleming mentioned that it would be bad to have iron in the dynamometer. They had overcome his difficulty. They had the cylinder of iron, which was pivoted between two fixed points in the usual manner, to have the friction as small as possible. It carried two iron arms, which were very thin and flat, and at right angles to these arms it carried a pointer the same as in the other dynamometer. At the top was a spring which counteracted the influence of the current. Even with a very small current these two thin iron arms were magnetised to their greatest extent, and they had an instrument which would read from 10 to 320 degrees, and could be used in any position, the moving parts being balanced, and there not being a single loose contact in the instrument. This was a very handy instrument to be used on board ship. In order to avoid getting permanent set in the spring it was always advisable to have a switch, take the reading, and take the instrument again out of circuit. For measuring the volts of an alternating current the instrument brought forward by Prof. Ayrton as an improvement of Captain Cardew's was of course very much better adapted.

[We are indebted to Mr. Siemens for the accompanying drawings of the instrument, together with the following detailed description:—Fig. 1 is a vertical section, Fig. 2 a sectional plan, and Fig. 3 a front view showing the part immediately underneath the dial. The same lettering applies to each figure.

A is an iron spindle delicately pivoted at its ends where there are two iron arms a a projecting from it in opposite directions. Around the spindle A there are conducting coils B consisting, for the electro-dynamometer, as shown in Figs. 1 and 2, of a few convolutions of copper bar of rectangular section helically wound without contact with each other, but in the voltmeter, consisting of numerous convolutions of fine wire. In either case, when the currents traverse these coils, the arms a a constitute polar extensions of the solenoid core A.

As shown in Fig. 1, the current entering by the post C passes along a metallic framing C^1 C^2 C^3 through the coil B and out by the post D or in the reverse direction. In passing along the parts of its circuits C^1 and C^3, which are parallel to the arms a a, it tends to deflect them and so to turn the spindle A partly round, with more or less force according to the strength of the current.

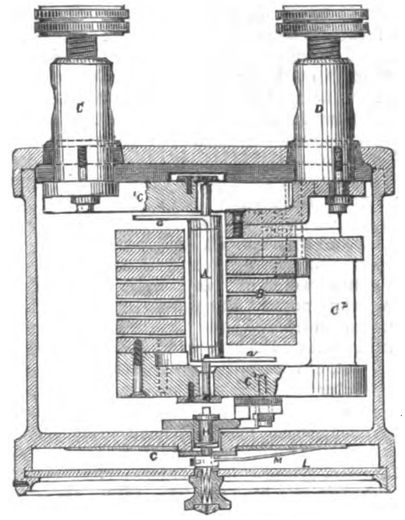

FIG. 1.

At the front end of the spindle A is fixed a light index wire F, which may be of aluminium. It is counterbalanced by an adjustable weight F^1 and is bent forward so as to project through a hole in a dial G. Through this dial passes a central spindle H, which can be turned by hand and which

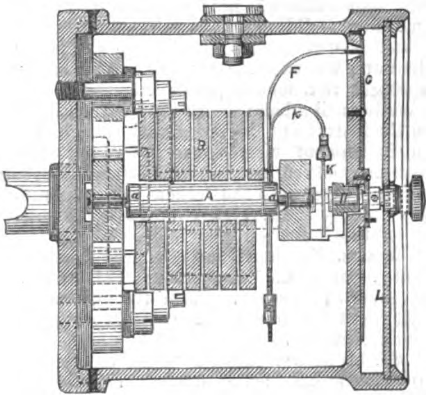

FIG 2

has fixed to its inner end the innermost convolution of a volute spring, K, Fig. 3, the outermost convolution of which is connected by an arm, k, to the index wire F. On the spindle H, outside the dial G, and protected by a glass, L, there is fixed an index, M, pointing to graduations on the dial.

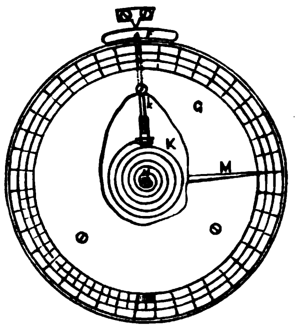

FIG. 3.

When the instrument is put in circuit, the spindle H is turned by hand until the force of the volute spring K is made to balance the force tending to turn the spindle A by deflecting the arms a a, as can be seen by observing the point of the wire F just vibrating within the hole of the dial through which it passes. The reading is then taken direct from the dial, no separate table of values being required.]

Mr. GORDON said he thought it opportune to bring to the notice of the society an instrument which was manufactured in Germany and had not been much seen in England. Mr. Gordon then described Dr. Aron's well-known current meter. He brought it forward, he said, because it was now in a practical form for actual use. As they were dealing with the scientific aspect of the question they must remember that the principle belonged to Profs. Ayrton and Perry. In fact, he thought he might go so far as to say that the makers had offered to recognise the share which Profs. Ayrton and Perry had taken in its original design. He (Mr. Gordon) had not tried the

Digitized by Google

meter himself, but Mr. Frumpet said he had found it extremely accurate and extremely practical.

Captain CARDEW having made a few observations on a small portable voltmeter which he introduced as a curiosity,

Mr. ESSON said, speaking as a maker and user of electrical measuring instruments, he could not see that the form of instrument introduced by Dr. Fleming possessed any advantage over several forms already before the public and in the market. All that Dr. Fleming's voltmeter was capable of doing could be performed by a finely-wound Siemens dynamometer, and that without taking the current through the spring, which was, he thought, decidedly objectionable. They knew that the elasticity of springs remained under ordinary conditions very constant for long periods, but it was doubtful whether in the present instance the value of the constant would not be altered by the continuous heating and cooling, or expansion and contraction due to the currents flowing through the spring. He presumed Dr. Fleming meant his instrument to be used only as a standard and not for installation work. For the latter they required indicating instruments, which would show from moment to moment the E.M.F. or current flowing. Zero instruments, in which, before an observation was made, the movable part had to be balanced by the observer, were quite unsuitable for installation work. As regarded wattmeters, he greatly doubted whether the profits to be derived from their sale compensated for the trouble of designing them. Out of some thousands of instruments sold by his firm they had only managed to dispose of some half-dozen wattmeters. It seemed to him that these instruments were of very little use. People not only required to know the power expended in the circuit, but also how the product of amperes and volts was made up. Dr. Fleming truly said that that could be obtained by a wattmeter and voltmeter, but, of course, it could be equally well obtained from an ammeter and voltmeter. Mr. Esson then described one that measured 2,500 amperes, and was designed by Sir William Thomson. It consisted of a movable ring, supported above a fixed ring, the former being suspended by two ligaments, each consisting of 900 copper wires, one-tenth of a millimetre diameter, lying side by side. The bottom ends of the ligaments were attached to two pins projecting from the sides of the movable ring towards its interior, the top ends to two pins fixed above those. The current divided on the movable ring, half going round each side, while on the fixed ring it circulated in one direction only. There was, consequently, attraction between the fixed and movable rings on one side from parallel currents, and repulsion on the other side from currents in opposite directions. The force tending to tilt the movable ring was balanced by a sliding weight, its position indicating the current flowing. The instrument was a very difficult one to use. When the scale beam was nearly balanced the slightest pull on the cord which moved the sliding weight was sufficient to make the beam kick dreadfully, and it was almost hopeless to attempt balancing the current unless the latter was extremely steady. As a matter of fact, they had to move the weight to a definite position, and reduce or increase the current very gradually until a balance was obtained, noting at that instant the deflection on the instrument in series with it, which is being calibrated. A spring instrument, where the force was put on very gradually, was much easier to use; but springs, on the other hand, might lack the constancy of weights. Coming to the Cardew voltmeter and the ingenious modification introduced by Profs. Ayrton and Perry, he noticed several of the latest forms of the former on the table. In the particular instrument made by Messrs. Paterson and Cooper there were expended about forty watts, and the temperature of the tube rose to about 150deg. F., he should think. From the figures given to him by Prof. Ayrton last week he found the watts expended in his instrument about the same; but from the fact that with his the radiating surface was very small, he should think it would rise to a very high temperature. The question would then arise whether the heating and cooling would not affect the permanency of the springs. Prof. Ayrton said that a certain initial sag had to be given to the wire. He should like to know what adjustment there was for ensuring that the sag would be the same when the instrument was re-wired. In an instrument constructed on the Cardew principle it was most important that the least difficulty be experienced in re-wiring should the wire break or fuse. In the form made by his firm, the wiring was most simple. Though he had never re-wired an instrument, he never considered it a very formidable task until he saw Prof. Ayrton's. His instrument he thought must be very difficult to wire. Probably the best way to determine whether the new or the old form were the easier would be to have a race. Prof. Ayrton would start re-wiring his and he (Mr. Esson) his, and the one who finished first would be the winner (laughter.)

Mr. EVERSHED said like every one else he was very much delighted with the appearance of Dr. Fleming's instrument. Everyone had said something about the spring. He should certainly prefer an instrument if the current were not led through the spring. No one had said anything about the temperature errors of springs. He had not had much experience of them, but he suspected they had a kind of temperature coefficient. He should very much like to know whether they had, or whether they were simply spoiled by rise in temperature. He was rather surprised that Dr. Fleming should have used platinoid in one of his instruments, for so far as his experience went if they wound an instrument of that type with copper and put platinoid in series with it, they expended less power than if they wound with platinoid. Of course then there was the error after heating, but that could be compensated by the method devised by Mr. Swinburne, and communicated by him to the British Association at Manchester. Dr. Fleming's instrument could be easily compensated. As to the wattmeter, he did not agree with Mr. Esson about the uses of wattmeters. Of course he was speaking of those used in engine works. His (Mr. Evershed's) experience had been in lamp factories, and Dr, Fleming's was intended for use in the lamp factory. For many months he used a roughly-made direct-reading instrument, not zero reading, and he calibrated that in candles. A girl about 14 tested an enormous number of lamps by that wattmeter. She conducted the operation most happily, and was singing hymns all day (laughter). With this particular instrument before them she might have got through a great many, but he did not think she would have sung the hymns (renewed laughter). He had intended saying something about the compensation of instruments in general. The subject was brought to the notice of the public by Mr. Swinburne, at Manchester, and he had been working at it practically for some time. His instrument was not ready yet, but he hoped early next year to be able to bring it before the society. Coming to Profs. Ayrton and Perry's low-reading voltmeter, it seemed to him admirably adapted for testing secondary cells. There was a distinct want of instruments reading up to 5 volts; they had not been able to bring out a satisfactory instrument, although many experiments had been tried. Profs. Ayrton and Perry seemed to have objections to gearing. If they wanted an instrument that could be knocked about by an engine driver, the Cardew voltmeters they saw on the table were thorough engineers' instruments. They were solidly made, and the use of gearing enabled them to do away with the objectionable silk passing round the axle. It was very difficult to get good gearing, but the perfect curves which they got from this instrument showed that the rate at which the pinions turn exactly corresponds to the rate of the wheel. Mr. Esson said something about the power spent, but he must have been simply thinking of the spring. He had already asked Dr. Fleming about the effect of temperature on the springs. There was another point which occurred to him. In the small instrument, reading up to 10 volts, the loss appears to be very small. He thought it worked out at not more than 2 watts. In the instrument reading up to 170 volts the power spent was something like 50 watts. In their instrument they found that a radiating surface of about 5 to 7 square meters would do for a watt, and they got quite enough heat at that. He was quite sure they could not leave the new instrument "on" at 170 volts. One of the charms of the Cardew instrument to him was that they *could* leave it on. He had come across a very interesting point in making Cardew voltmeters with respect to the energy of radiating by fine wires and thick wires. If they had a given length of wires of different thicknesses and passed the current through you raise them to the same temperature, taking the deflection on the dial as indications of the temperature. They did not know what the temperature was, but they knew it was the same temperature if they had the same deflection, provided the position of the wires be the same It might have been expected that it would take less power to keep the fine wire at the temperature than it did the thick; but he found it did not. In the first experiment the fine wire positively took more power. He repeated the experiment more carefully. He had taken one volt, and used strains proportional to the breaking weights of the wires. The different sizes of the wire were 1·5, 2·5, 3·5. The wire was in the same position on each occasion, and he raised it to 280 degrees deflection, which he knew corresponded roughly to 200 degrees centigrade, and the indications were 1·4—38·2, 2·5—36·9, 3·5—32·2. He would not at the present time say these figures were exactly right, because one did not know the exact position of the wire, and it was absolutely essential to know that; but it was quite clear that the power did not diminish as the size of the wire diminished.

(This Discussion will be concluded in our next.)

THE COST OF CENTRAL STATION LIGHTING.

A valuable and interesting article under the above title appeared in *Industries* of December 2nd. The article is too long for reproduction in our columns, but we would recommend every electrical engineer to make a point of reading it. Meanwhile we present the following summary of its contents:—

The writer proposes to institute a general comparison between the cost of lighting from central stations on the three systems which admit of distribution by means of high tension in the mains with low tension on the supply circuits. In these systems the necessary transformation may be effected—(A) by storage batteries, (B) by rotary transformers, (C) by alternating current transformers. After a preliminary discussion of the particular advantages and disadvantages of the several systems (matters which are, however, within the cognizance of every electrician), the writer proceeds to compare their relative economy in a given case, "taking as an example a central station plant capable of maintaining 10,000 glow lamps of 60 watts each, simultaneously alight, a capacity which will probably suffice for a total of 15,000 lamps fixed." The other working data are taken as follows:—

Annual hours of burning	1,500
= Total lamp hours per diem	60,000
= Board of Trade units per diem	3,600
Maximum rate of supply	600 kilo-watts.
Distance from charging station to centre of district	2 miles.

(A) BATTERY SYSTEM.

Total storage of batteries	4,000 units.
Maximum output	1,000 kilo-watts.

The margin is considered necessary for safety.

It is assumed that each sub-station supplies 2,000 to 3,000 lamps.

Digitized by Google

(A) Storage Batteries in Sub-Stations.

Total storage capacity required	4,000 units.
Maximum output required	1,000 kilo-watts.
The battery is preferably divided into two unequal sets of cells for day and night service respectively.	
Output of smaller battery	350 kilo-watts.
,, larger battery	650 kilo-watts.
Efficiency of batteries, including regulating appliances	75 per cent.
Charging current for larger set	160 amperes.
Under an E.M.F. of	2,000 volts.
Charging period	10 hours.
Loss of energy allowed in charging mains	10 per cent.
Maximum output of dynamos	355 kilo-watts.
Add 20 per cent. of reserve dynamo power	430 kilo-watts.
Necessary steam plant	700 I.-H.-P.

Cost—

Cells at £30 per kilo-watt maximum output	£30,000	
Supply mains at £1 per lamp	15,000	
Dynamos at £8 per kilo-watt	3,440	
Engine and boilers (including foundations, shafting, and all accessories) at £12 per I.-H.-P.	8,400	
Charging mains, exclusive of attachments (allowing for loss of 200 volts)	1,600	
Regulating appliances at sub-stations	1,000	
		£59,440

or, say, £60,000, which is at the rate of £4 per lamp fixed.

(B) Rotary Transformers in Sub-Stations.

Commercial efficiency of transformers	85 per cent.
Maximum rate of supplying energy on primary circuit	700 kilo-watts.
Loss of energy allowed in primary circuit	10 per cent.
Output of dynamos	775 kilo-watts.
At 2,200 volts this gives current in circuit	350 amperes.
Adding to output 20 per cent. reserve power	930 watts.
Necessary steam plant	1,500 I.-H.-P.

Cost—

Transformers at £10 per kilo-watt	£7,200	
Dynamos at £8 p r kilo-watt	7,440	
Steam plant at £12 per I.-H.-P.	18,000	
Feeding mains for 350 amperes, exclusive of attachments	3,300	
Supply mains at £1 per lamp	15,000	
Regulating appliances	500	
		£51,440

or, say, £52,000, which is at the rate of nearly £3. 10s. per lamp.

(C) Alternate Current Transformers on Consumer's Premises.

In this case, as every consumer must be supplied with a transformer capable of feeding the whole of his lamps at once, the transformer plant must be equal to an output of 15,000 lamps instead of 10,000, as in (A) and (B). The dynamos, however, need have only the same output as before.

Average number of lights per transformer taken at	100.
Number of transformers required	150.
Total maximum output of transformers	900 kilo-watts.
Efficiency	93 per cent.
Maximum rate of supplying energy on primary circuits	645 kilo-watts.
Loss of energy allowed in primary circuit	10 per cent.
Output of dynamos	720 kilo-watts.
Adding 20 per cent. reserve power	865
Efficiency of dynamos, including 3 per cent. of output required for exciters	80 per cent.
Steam power required	1,450 I.-H.-P.

Cost—

Transformers at £4. 10s. per kilo-watt	£4,050	
Alternate current dynamos at £6 per kilo-watt	5,190	
Exciters	350	
Steam plant at £12 per I.-H.-P.	17,400	
Feeding mains (as in B)	3,300	
Regulating appliances (as in B)	500	
House connections	600	
		£31,390

say £32,000, which is at the rate of a little under £2. 3s. per lamp fixed.

The article concludes as follows :—" A glance at these figures will show the enormous superiority in point of capital expenditure which the alternating current system has over its two rivals. In making the above estimates we have, as stated in the beginning of this article, left out of consideration the question of motive power, because in the immediate future this branch of the business need hardly be taken into account. The use of electricity for lighting must always precede its general application for motive-power purposes, and it would be unwise to allow the latter to play too important a part when deciding upon the system to be adopted. If, however, motive power were taken into consideration, then rotary transformers would offer a distinct advantage over batteries, inasmuch as their capacity need not be increased on this account. Motive power will be principally required during the day and light during the evening, so that without a further increase in the cost of the central station or that of the transforming plant, a considerable call for motive power could be met. With the batteries this is not so. We have estimated for a capacity just sufficient for lighting purposes only, and if motive power is to be supplied during the day, larger batteries would have to be installed. The alternating system, on the other hand, may at present be said to be quite unfit for the supply of motive power. Experiments have been made with a view to develop motors driven by alternating currents ; but up to the present the results obtained are not of such a nature as to justify any electrician to include the supply of motive power in his scheme when laying out a central station on the alternating-current system. That ultimately the difficulty of obtaining motive power from alternating currents will be overcome by the invention of a suitable motor may reasonably be expected, and if this result is achieved the superiority of the alternating system over either battery or rotary transformer will be still further enhanced. As matters are at present, we may sum up the foregoing by stating that the expenditure for plant is about equal, whether secondary batteries or rotary transformers are used, and that it is little more than half when alternating currents and transformers are employed."

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

New York, Nov. 24th, 1887.

The endeavours now being made in England to form an association which will deal in a representative way with the commercial interests of electrical engineering are watched with no small interest in this country. The work of such an association would, it appears, be confined chiefly to the department of electric light and electric power, and hence it would closely resemble the American National Electric Light Association, to which reference has so frequently been made during the discussion of the subject. It is to be borne in mind that the American body is very largely composed of the representatives of local electric lighting companies of all the various systems, except the Edison, which has an association of its own. The National Electric Light Association does not indulge in scientific discussions—these are, in fact, forbidden by its constitution—but twice a year it brings a very large amount of experience, common sense, and business ability to bear on the practical details of an industry growing more rapidly than any other, perhaps, in this country. Under the brilliant and energetic direction of its president, Mr. J. F. Morrison, of Baltimore, the Association has done good work, and although the lines of its future action cannot yet be said to be determined it will undoubtedly find with the expansion of the business enlarged opportunities of usefulness, and will live up to them. The visits of the body to various parts of the country for its semi-annual meetings have been of immense benefit in arresting popular attention to the vitality and prosperity of the industry, and have given marked stimulus in each place to the use of electricity for all purposes.

With the approach of winter the number of English visitors is notably reduced. One of the latest to remain is Mr. M. Holroyd Smith, whose work at Blackpool is so well known and was so recently celebrated with unusual honours. Next week Mr. Smith is to give the New York Electrical Society a "Talk on Tramways," and the occasion will no doubt be one of much interest and profit to the members.

The Electrical Exhibition which has been given in this city under the auspices of the Society draws to its close. It has been in many respects a marked success. Nothing of the kind had ever been attempted before in New York, and despite the extensive use of telegraph, telephone, and electric light here, the ideas of the general public on the subject of electricity

Digitized by Google

have been very vague and crude. The society can justly claim to have done some excellent educational work this autumn, and there will be many appreciable results. A special and very prominent feature of the Exhibition has been the motor display, which has included illustrations of the uses of electricity as a motive power in well nigh every department of industry dependent on machinery. The attendance throughout has been good and of a high character.

A noteworthy feature in cabling was performed this week by the *New York Times* in its publication of Mr. Swinburne's new tragedy "Locrine." This tragedy, comprising about 18,000 words, was forwarded by Mr. Harold Frederic (the *Times* correspondent in London) over the Commercial and Western Union cables, and was published promptly next morning. About five hours were occupied in transmission, and the work was remarkably well done. Some of the journals are inclined to belittle this piece of enterprise, and to question its utility, especially those which had secured advanced sheets from the American publisher, and had put the matter in type awaiting the intimation to "go ahead." The *Times* has distinguished itself in this respect once or twice before, and in 1884 obtained by cable the whole of the Spanish United States Commercial Treaty. The latest feat eclipses everything, and is seconded by a piece of work done by the Associated Press in handling one of Mr. Gladstone's big speeches.

The whole of the past week may, in fact, be said to have been one in which cable interest predominated. At the joint meeting of the American Institute of Electrical Engineers and the New York Electrical Society, on the 15th inst., Mr. Charles Cuttriss presented an able and instructive paper on "Improvements in Apparatus for Ocean Telegraphs." This was supplemented by an interesting communication from Mr. T. D. Lockwood, and was followed by a brief but animated discussion in which ocean telephony, for the present at least, received a *quietus*. Among those present was Capt. Trott, of the Anglo-American cable repairing steamer, "Minia," which has been in port here at the Erie Basin dry dock, undergoing repairs rendered necessary by damage sustained in heavy weather in the North Atlantic. The "Minia," as is probably well known in England, was not specially constructed for cable work, but under the command of Capt. Trott she has rendered first-class service. The steamer has been visited by a number of electricians, being very much a novelty in these waters. All have been hospitably received, and many have realised for the first time the magnitude of the difficulties involved in maintaining intact the slender lines of cable that stretch between the Old and the New World.

Work is about to cease for the winter on the new subways. For months past a number of our main thoroughfares have looked like those of Paris in times of *emeutes* and barricades, and many of the citizens who were loud in their complaints against the aerial wires have been warmest in their denunciations of the present condition of things. The work that has been done has yet to undergo the practical test of operation and of time, and it will be years before any real solution of the problem will be arrived at. It is somewhat significant that latterly our Board of Electrical Control has been seriously discussing the best type of electric light pole, and that under one of its permits an order has actually been placed for 250 miles of aerial electric light wires, Nos. 4 and 6. This magnificent order, I may perhaps mention, was secured by the Callender Company. In other cities the old fight between the electric companies and the city authorities as to burying the wires goes on without much net result.

Although the decision of the United States Supreme Court in the Bell patent case has now been expected for some time, it has not yet been handed down, and uncertainty reigns supreme. The stock of the American Bell Telephone Company remains firm at high quotations, in spite of mysterious reports and whispers as to the intentions of the Court. The decision may come next week, and it may not come until January. Should it be in any degree unfavourable, there will be a tremendous outburst of telephonic speculation, for which even now preparations are being made; but the present Bell system is strong enough probably to withstand assault from every quarter.

Mr. Gould's mission to England is variously regarded and as variously commented on. It is understood that he seeks once more to have Western Union listed on the London Stock Exchange, and it is said that the house of Baring is his agent in the matter. Mr. Gould's wishes and aims are known, however, to no one but himself. From the course taken by affairs in the New York Stock Market since he sailed away, it is to be inferred that he finds it as easy to direct operations here as though he sat in his office on Broadway instead of being within sight of the Peabody statue.

CORRESPONDENCE.

THE DISEASES OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the discussion on the above I am reported in your issue of the 2nd inst. to have thought "that unequal sparking of brushes was due to the field being made unequal by the presence of masses of iron about one of the poles." What I really *said* was as follows:—"There is a tendency to unequal sparking in some machines where a Gramme armature rotates between the poles of a single horseshoe magnet, owing to the lines of force dividing unequally in the two halves of the armature. More lines go through the half nearer the yoke than the farther half, and the brushes in consequence may have to be adjusted not quite opposite each other. In machines where the magnet is reduced to half its thickness by boring out to form the polar recess this tendency becomes noticeable, but as the thickness at the poles is made greater the tendency disappears. With the drum type of armature it does not exist, as each convolution of conductor embraces *all* the lines of force, and not half only, as in the ring type." It might be possible to obtain a more equal distribution of field in the two halves of the armature by placing the latter excentrically in the field, its centre being rather further from the yoke than the centre of the polar cavity.—Yours, &c.,

W. B. ESSON.

London, Dec. 5th, 1887.

SPRINGS ON TELEGRAPH WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: No writer in your columns has yet called attention to the following fact, which is the most vital in determining the range of relief which the springs are able to render the line wire under excess loads.

That fact is that *the relief increases much faster than the stress.*

If we set the 100lb. copper wire, of 100 yards span, up to a tension of 82·5lb. at 22deg. F. with springs, as we should set it to the same 82·5lb. stress without springs, we practically disallow relief, making it *nil* at that starting point.

Then let the falling snow and rising wind increase the stress to 165lb.

Then the springs will give the line wire relief equal to a horizontal wind force of no less than *5·6 foot-tons* on every pole 20ft. high to centre of pressure, carrying 20 wires, each wire laden with 24lb. of snow per span, and *the springs give this enormous relief without themselves or the wire being in the slightest degree overstrained.*

Unaided by springs, the line wire, when loaded with 24lb. of snow per 100 yards span, could not sustain any wind pressure at all without being overstrained.

It is because the spans as now hung are mostly only about 66 yards that the lines stand as they do.

If these 66-yard spans were all furnished with springs the problem would no longer be how to preserve the *wire*, but how to sustain the *posts* against storms; for certainly the posts would give way first unless powerfully stayed.

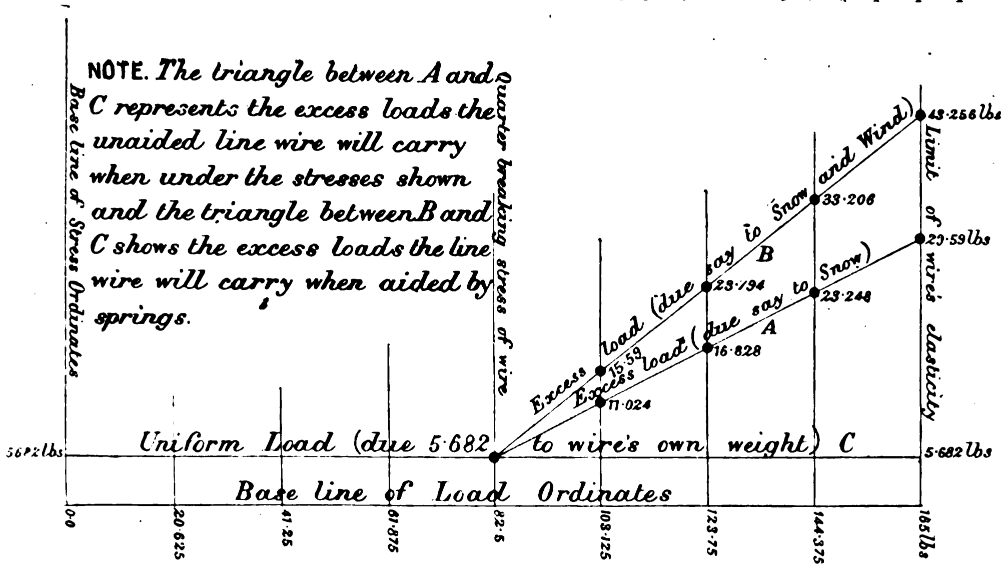
I append a diagram and table, which will speak for themselves.—Yours, &c.,

FRANK CAWS.

Sunderland, Nov. 26th, 1887.

Digitized by Google

DIAGRAM showing relief afforded to a 100-yard span of 100lbs. copper wire, by springs stretching ·4674ft. per span per 82·5lbs. stress.



NOTE.—Occasionally the weight of snow on a wire equals, or even exceeds, 24lbs. This diagram shows that the line wire has no reserve elasticity for such wind pressure as may be encountered when the 24lbs. of snow tube is present. But the springs give the required reserve to enable the wire to resist such wind pressure.

TABLES SHOWING THE EFFECT OF A GATHERING LOAD OF SNOW AND WIND ON THE STRESS OF A 100-YARD SPAN OF COPPER WIRE WEIGHING 100LB. PER MILE.

NOTE.—The modulus of elasticity (14,500,000lb. per inch) which I have used in these tables is low, for doubtless it is in very hard wire often as high as 16,900,000lb. per inch, or thereabouts. But in view of many practical contingencies I think the modulus I have used will give results very nearly true. The effect of a higher modulus would be to reduce the dip and load for a given stress, and to increase the dip and reduce the stress for a given length of expansion. Books of reference differ as to the modulus for copper wire, and doubtless the wire itself differs also; but judicious experimenting would soon discover a good average modulus.

TABLE A.—Line Wire without Springs.

Stress.	Stretch of Wire.	Length of Catenary.	Span.	Dip.	Load.
lbs.	ft.	ft.	ft.	ft.	lbs.
0·000	·0000	299·71346	300·0	0·0000	5·682
82·500	·3459	300·05936	300·0	2·5842	5·682
103·125	·4324	300·14586	300·0	4·0508	11·024
123·750	·5188	300·23226	300·0	5·1114	16·828
144·375	·6053	300·31876	300·0	5·9884	23·248
165·000	·6198	300·40526	300·0	6·7522	29·590

TABLE B.—Line Wire with Springs.

Stress.	Stretch of Wire.	Stretch of Spring.	Length of Catenary.	Span.	Dip.	Load.
lbs.	ft.	ft.	ft.	ft.	ft.	lbs.
0·000	·0000	·0000	299·71346	300·4674	0·0000	5·682
82·500	·3459	·4674	300·05936	300·0000	2·5842	5·682
103·125	·4324	·5843	300·14586	299·8331	5·4349	15·590
123·750	·5188	·7012	300·23226	299·7662	7·2381	23·794
144·375	·6053	·8180	300·31876	299·6494	8·6726	33·206
165·000	·6918	·9349	300·40526	299·5325	9·9012	43·256

NOTE.—In these tables, as well as in the table published in *The Electrician*, November 4th, page 540, the slight difference between the catenary and parabola is neglected, as being of no practical moment where the dips are so small in proportion to the spans.—F. C.

STATIC *VERSUS* DYNAMIC BALANCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of last week Prof. S. P. Thompson is reported to have said "Every engineer worthy of the name knows that . . . a four-pound weight at 3in. from the axis of rotation, though balanced statically by a one-pound weight at 12in. from the axis, is not balanced dynamically, for the moments of inertia about this axis are not equal. On the contrary, a four-pound weight at 5in. is balanced dynamically by a one-pound weight at 10in." I am afraid I am not worthy of the name of an engineer, or I do not know what dynamical balancing means. I have been in the habit of thinking that, provided the axis of rotation were a principal axis through the centre of gravity, a rotating body would be balanced dynamically in the sense of there being no stress on the axis, whatever the speed of rotation, and that the balancing of the system did not involve the moments of inertia of the parts. If this is so, a four pound weight at 5in. from the axis, and a one pound weight at 10in. on the opposite side, if set spinning would produce the same stress on the axis as a two pound weight at 5in. unbalanced by any weight on the opposite side, while the four pound weight at 3in. and the one pound weight at 12in. would balance each other. The four pound weight at 5in. and the one pound weight at 10in. possess the same kinetic energy if small enough; but can Prof. Thompson use the word "balance" in this sense?—Yours, &c.,

Mk^2.

THE TRAINING OF ELECTRICAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your article on the above subject, and in the correspondence last week, I see that the idea prevails that the student, after having completed a course of electrical engineering at a technical college, is launched straight into the profession of electrical engineering—he is supposed to know the practical work as well as the theoretical. Now, the plan of my college, and of one or two others I know of, is to begin the education of the student by courses in mathematics, engineering, physics, mechanics, drawing, and electrical laboratory, the course being precisely the same as the mechanical engineering students go through; then, after he has completed his course he is assisted to get into some work as an articled pupil, where he will learn the practical part of the subject; but the prospect of his obtaining a paid appointment direct from the college is hardly entertained at all. I should think it would be impossible for any college to teach the practical part of electrical engineering as it is taught in works.

The opinion of your correspondent, Mr. Walker, concerning theoretical knowledge is not universally held by all firms, one of which I know offering to waive premium for theoretical knowledge. Apologising for taking up your valuable space,—Yours, &c.,

AN ELECTRICAL ENGINEERING STUDENT.

PHŒNIX FIRE OFFICE RULES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: May I ask you on behalf of the Phœnix Fire Office, and in order to set ourselves right in the eyes of the public as well as of our competitors, to allow me to explain that the "Phœnix Rules for Electric Lighting Installations" (to which your journal has recently borne favourable testimony) do not lay claim to any formal sanction by the Fire Offices Committee. If any merit belongs to these "Rules" it is due to their practical value as tending to promote safety from fire, and thus to protect an approved mode of lighting from any unfair suspicion of danger.—Yours, &c.,

F. B. Macdonald, Secretary.

Phœnix Fire Office, 19, Lombard-street, London, E.C., 6th Dec., 1887.

PRIMARY BATTERIES FOR HOUSE LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I quite think with Mr. Ross that the primary battery has a useful sphere of action, even as a lighting agent; but unless Mr. Ross can show at the proposed trial that expenditure in oxydising liquid need not be more than that for zinc, I fear it will be extremely limited.

On referring to Mr. Nursey's paper I find the cost of fuel in the Holmes and Burke battery to be 8s. 6d. for five electrical horse-power-hours, or 1s. 8½d. per electrical horse-power-hour, and that the labour and attention required for a battery of this output would range from a quarter to half an hour per day, with one hour per week for recharging. On this basis I have constructed the above table, which serves to show the approaching limit at which such a battery could successfully compete with an engine and dynamo.

The sum fixed for labour on battery is the minimum that I conceive an experienced man would ask for the attention required.

In considering the question of engine labour, it must be remembered that a man at 30s. per week, with only a one horse-power installation on his mind, would in most cases be employed on other useful work; nor is it impracticable for the householder to work his own engine, and only benefit by such labour as would be required for a battery. In such a case the difference in working cost would be very considerable, and would approach to $\frac{1}{10}$th that of a battery. It is to be hoped that, if the trial in question comes off, the details of working cost will be specified per electrical horse-power-hour and not per lamp-hour, which may mean anything, according to the point of efficiency at which the latter is worked.—Yours, &c.,

N. G. Thompson.

4, Queen Victoria-street, London, E.C., Dec. 6, 1887.

TENSILE STRENGTH OF ELECTROLYTIC COPPER.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: While the late action of Elmore *v.* Pirrie was being tried before Mr. Justice Kay, Messrs. Goodwin and How, civil engineers, of Westminster, who were engaged in the case, called my attention to a statement in my work "Electro-Deposition" relating to the tensile strength of copper, which is erroneous and misleading, and I shall esteem it a great favour if you will kindly allow me to correct that statement in the columns of your widely circulating paper. On page 144 of my book a comparison is drawn between the tensile strength of sheet copper as manufactured by the ordinary process and copper deposited by the Hallett-Elmore dynamo, which would lead readers to believe that the latter material broke under a tensile strain equal to 32 tons per square inch of original area, which is not the fact, and I find that Mr. Elmore, who gave me those figures in his own handwriting, had taken from Mr. Kirkaldy's certificate the stress per square inch of the *fractured* area, and coupled that with the elongation. The certificate referred to, which was produced in court during the trial, shows that the copper stood 15·2 tons per square inch of original area, and elongated 38·2 per cent. To ascertain the comparative strength of electrolytic copper deposited very slowly and ordinary copper, Messrs. Goodwin and How carried out a series of trials, the results of which showed that the latter was the stronger of the two. Trusting you will favour me by inserting this explanation.—Yours, &c.,

Alexander Watt.

THE CONDUCTIVITY OF GLASS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Mr. Cherrill, in his "Notes on the Conductivity of Glass," *Electrician*, December 2nd, 1887, has omitted to mention that the phenomenon of the semi-decomposition of the lead glass in our lamps by an electric current aided by heat, was pointed out by me, and proved by Mr. C. H. Stearn, managing director of our company, to be electrolytic action.

Digitized by Google

The following, which may be of interest, is quoted verbatim from a letter dated February 26th, 1885, which Mr. Stearn kindly sent me referring to the subject. I was then submanager under Mr. Cherrill.—Yours, &c.,

C. FARADAY PROCTOR.

70, Rue des Sarrazins, Lille, 3rd December, 1887.

"My dear Mr. Proctor, February 26th, 1887.

"I have to thank you for pointing out the continuance of the black deposit to which I formerly directed your attention, and for the close observation which has traced it, at least in part, to a cause that was not then suspected, viz., electrolytic action. I have embedded flat plates of platinum in a block of the glass, and produced the blackening in less than one minute, the glass being very hot. I reversed the current, and then got the second pole black. But the most important point I want you to observe is, do small gas bubbles appear on the other pole in the glass? for in every experiment I managed to blow large bubbles in the glass with the gas evolved. If this takes place, it of course sets up leakage and accounts for bad vacua.—Yours very truly,

"(Signed) C. H. STEARN."

MR. WEBSTER'S CHALLENGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reference to the letters of Messrs. Ross and Shippey, my only conditions are that the cells of competing batteries shall be of similar size—say, of one gallon capacity (surely, this does not exclude any *shape?*), and they must not be colourable imitations of mine.

I leave all other matters to the arbitrator; he, of course, must judge for himself. My offer remains as before; the competition being purely for scientific reasons, and not for commercial purposes. It having been stated that primary batteries will not answer for lighting, I want to prove the fallacy of such a statement; but having a particular battery of my own construction I cannot judge impartially of the merits of others.—Yours, &c., WILLIAM WEBSTER, JUN.

P.S.—My battery has very little in common with the "Holmes-Burke."

TRADE DISCOUNTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am quite prepared to join issue with Mr. Fricker on the question of the advisability of the use of advanced mathematics in ordinary business transactions, such as the one referred to, or upon any other question upon which we may happen to hold different opinions, but I must stipulate that he fights fair, or I shall leave him the field to himself.

I maintain that it is not only practicable but greatly to the advantage of discussions on subjects such as are admitted to your columns that personalities of all kinds should be avoided. The time occupied in considering how to give your adversary *one* that will make him feel, and the time occupied in recovering from the *one* that he usually returns would be very much more profitably employed in considering how you are to meet his argument.

Now, as to the matter in hand. My rule was taken from actual practice of years past, and was not deducted from Mr. Money-Kent's formula, though, of course, it follows that unless either my rule or Mr. Kent's formula be wrong they must work out to the same figures.

Next, I maintain that for one boy or clerk who could work from Mr. Kent and Mr. Fricker's formula, however simple it may seem to them, at least a hundred would be found who could work quite easily from my rule, and a great many could figure out the principal discounts in their heads.

Mr. Fricker and Mr. Kent appear both to have been unfortunate in their business experience in this matter; but I hardly see that, because they have had certain peculiar experiences, it should be assumed that all business transactions are conducted in the same slipshod manner; and still less am I able to understand how the matter is to be improved by the use of a formula that would be absolutely unintelligible to nine-tenths of those who are supposed to use it. It is clerks and office boys who work out these figures, not heads of firms or managers; their time is usually too valuable. And there are daily, in the city of London, to go no farther, numbers of minute calculations worked out with reference to discounts and profits in houses where perhaps not a single member of the staff knows anything of advanced mathematics. Accountants do not use advanced mathematics.

Further, I took the opportunity presented by the appearance of Mr. Money-Kent's article to enter a protest against the growing tendency to drag mathematics into everything. I have as high an admiration of mathematics as any one, but I like them as servants, not as masters; and I like to take the shortest, simplest, and surest road to my object, which, to my mind, mathematics do not always furnish, certainly not in the present instance. Mathematics and theory are dangerous tools; you can never be certain that you are using them aright until you have clearly proved them by practice.—Yours, &c.,

SYDNEY F. WALKER.

[We think that this matter should now be allowed to drop. —ED. *E.*]

WORKING MEN'S CONFERENCE ON TECHNICAL EDUCATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: A conference on technical education has been arranged to take place at the Royal Victoria Hall, Waterloo Bridge-road, on Wednesday, 14th inst. Its object is that the employers and workmen, especially of this neighbourhood, may meet in a friendly way, together with others who take a special interest in the subject, and discuss it from their several points of view, particularly with regard to possible legislation. It is a matter equally important to masters and workmen, and their interests with respect to it are identical if they would but recognise the fact. We have requested that all parties will sink politics in considering it, and think only of the general welfare.

Sir Henry Doulton has kindly promised to take the chair, and two short papers will be read (one by Dr. Fleming, of University College; the other by Mr. Bockett, a working man), to be followed by a discussion. May I make known through your columns that I shall be happy to send a ticket for the platform or a reserved seat to anyone applying for the same?—Yours, &c., EMMA CONS, Hon. Sec. and Trustee.

Royal Victoria Hall, Waterloo Bridge-road, S.E.,
Dec. 7, 1887.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

16,376. C. B. NOBLE and R. D. NOBLE. London. Improvements in electric arc lamps (complete specification) November 29.

16,398. B. W. WARWICK. London. Automatic machines for the supply of liquids on draught by electrical and other means. November 29.

16,455. H. THAME. London. Improvements in secondary or storage batteries. November 30.

16,458. A. A. C. SWINTON. London. Improvements in electric telephones. November 30.

16,473. S. S. BROMHEAD. London. An electrical signalling device for railway purposes (S. T. Street, United States) (complete specification). November 30.

16,474. B. W. WARWICK. London. Improvements in automatic machines for the supply of electricity for medical and other purposes. November 30.

16,489. A. MELVILLE. London. The production of force (power) for mechanical purposes, superseding the use of steam or gas engines, more especially for the generation of electricity. November 30.

16,537. F. WYNNE. London. Improvements in or pertaining to means or apparatus employed in the application of electricity to propel vehicles; applicable also for other purposes. December 1.

Digitized by Google

16,554. G. BINTER. London. A new or improved electric apparatus for indicating distant water level, and similar purposes (complete specification). December 1.

16,558. A. WRIGHT. London. Improvements in apparatus for measuring and regulating electric currents (complete specification). December 2, 1887.

16,559. A. WRIGHT. London. New or improved means of and apparatus for measuring currents. December 2, 1887.

16,565. E. THOMAS. Battersea. Electrical measuring instruments. December 2, 1887.

16,583. F. C. PHILLIPS and H. E. HARRISON. London. A method of regulating electric arc lamps. December 2.

16,584. F. C. PHILLIPS and H. E. HARRISON. London. A method of controlling or regulating electric motors. December 2.

16,603. A. J. BOULT. Middlesex. Improvements in or relating to electric lamps for velocipedes or the like (R. Weber, Germany). December 2.

16,623. W. T. GOOLDEN and L. B. ATKINSON. Clapham. Improvements in dynamo electric generators and motors. December 2.

16,643. F. C. LYNDE. Manchester. Improvements in apparatus for indicating static or dynamic force or other measurements on prepayment of a coin. December 3.

16,669. M. BAILEY and J. WARNER. London. An improved secondary battery, combined with a miner's lamp (complete specification). December 3.

16,678. E. W. BECKINGSALE. London. Improvements in laying underground electric conductors. December 3.

16,717. P. A. NEWTON. London. Improved electro therapeutic apparatus (F. J. Kenenper, United States). December 5.

16,728. A. HEINTZ. London. Improvements in the manufacture of incandescent electric lamps (complete specification). December 5.

COMPLETE SPECIFICATIONS ACCEPTED.

NOTE.—*All persons interested in opposing the grant of a patent on any one of the undermentioned applications may, at any time within two months from the dates in italics, give notice at the Patent Office in the prescribed form of such opposition.*

December 3, 1887.

15,719. J. ROOTS. Kent. Improvements in apparatus for administering electric currents. December 1, 1886.

16,608. DESMOND G. FITZGERALD. London. An improved method for the production of coherent masses of peroxide of lead, for use as voltaic battery elements, and for use in electrolytical and metallurgical operations. December 17, 1886.

1,390. R. C. JACKSON. London. Improvements in dynamo-electric machines and electro-magnets. January 28, 1887.

1,609. W. J. BARNSDALE. London. Improvements in and connected with electrically wound clocks. February 1, 1887.

14,893. L. G. WOOLLEY. London. Improvements in generation of electricity. November 1.

14,908. C. R. GOODWIN. Paris. Improvements in electric batteries. November 2, 1887.

December 7, 1887.

15,774. I. PROBERT. London. Improvements in electrical switches and appliances connected therewith. December 2, 1886.

1,741. S. LUDWORTH and C. K. FALKENSTEIN. London. Improvements in apparatus for making and breaking electrical currents. February 3, 1887.

1,862. C. D. ABEL. London. For secondary batteries. (A. Dun and F. Hasslacher, Germany.) February 5, 1887.

1,929. C. D. ABEL. London. Improvements in galvanic batteries. (A. Dun and F. Hasslacher, Germany.) February 7.

PATENTS SEALED.

November 29, 1887.

13,987. J. G. STATTER and S. L. BRUNTON (Middlesex), J. W. KEMPSTER (Essex). An improved collector or brush for dynamo or magneto-electric machines or motors. October 30, 1886.

16,823. E. BARBIER and LECLANCHÉ. Paris. Improvements in electrical batteries, and in the manufacture of depolarising bodies to be used therein. December 22, 1886.

7,934. A. B. GILL. London. An improved electric switch. June 1, 1887.

December 2, 1887.

13,111. W. WARD. York. Improvements in electric lamps. October 14, 1886.

14,033. C. D. ABEL. London. An improvement in electrolysis (Siemens and Halske, Germany). November 1, 1886.

15,165. M. WILLIAM. Fulham. Improvements in the manufacture of incandescent electric lamps. November 22.

17,056. G. KAPP. Surrey. Improvements in dynamo-electric machines. December 29 1886.

3,749. K. MAXYMILIAN. Glamorganshire. Improvements in electrical apparatus for the prevention of corrosion and formation of scale in steam boilers. March 11, 1887.

7,079. E. WILSON. Germany. Improvements in dynamo-electrical machines. May 14, 1887.

11,356. C. RUNELS. United States. Improvements in electric couplings. August 19, 1887.

SPECIFICATIONS PUBLISHED DURING THE MONTH.

114, 1887.—W. A. LEIPNER. Dynamo-Electric, &c., machines. (Price 8d.)

13,092, 1887.—W. R. LAKE. (La Société A. Crute & Cie.) Carbon filaments for incandescent electric lamps. (Price 4d.)

13,454, 1887.—R. T. Turnbull. Incandescent electric lamps. (Price 6d.)

LEGAL INTELLIGENCE.

S. Z. Ferranti v. Gaulard and Gibbs.

This petition was mentioned before Mr. Justice Kekewich, in the Chancery Court of the High Court of Justice, on Monday. Mr. MARTEN, Q.C., said the matter arose on a petition which came before his lordship some time ago. The petition was by the plaintiff that he might be allowed to amend his petition by "correction, alteration, or disclaimer." It had been agreed between the parties that the words "correction and alteration" had been improperly used, and it was agreed, therefore, to amend the petition only by disclaiming certain facts. An order to that effect was made, and it was understood at the time that the terms were agreed to. The question arose on the drawing up of the order as to the amount of time to be given to them to disclaim.

Mr. ASTON, Q.C., interposing, said he did not know why this matter had been brought up again. As far as he knew the whole thing was settled, and he protested against the time of the Court being taken up in this way.

Mr. Justice KEKEWICH having sent for the Registrar who had the carriage of the order, Mr. Koe, and consulted with him, said: The dispute appears to me to be a most trivial one. He then made a slight verbal alteration in the order himself, which he initialled, and observed: It can now go. I shall not allow any costs on either side.

Sharp and Kent v. M. D'Humy.

MONDAY, DEC. 5th.—Before Mr. VEREY, Official Referee.

Mr. Noble (counsel) appeared for the plaintiffs, and Messrs. W. H. Smith and Son, solicitors, for the defendant.

This was the reference of an action upon a bill for carbons supplied to the amount of upwards of £100, the defendant bringing a counter-claim for £1,000 damages for loss occasioned to the defendant through the alleged badness of the carbon plates.

The case was opened before the Official Referee at a previous hearing on November 18th.

Mr. SMITH now said he had to ask for an adjournment by reason of the illness of the defendant D'Humy, and he produced two doctors' certificates in support of his proposal.

The OFFICIAL REFEREE, however, remarked that he saw no evidence on which to adjourn, and said: The defendant is not here, and unless you propose to call evidence to-morrow it is no use my adjourning. Are you prepared to pay money into court?

Mr. SMITH: Certainly; but our counter-claim being for £1,000, the other side must also pay in some amount.

Mr. NOBLE: Very well. We will pay into court £500 before 4 o'clock to-day, if the defendant will pay in £150 by same hour.

Mr. SMITH: I cannot agree to that in defendant's absence.

After some further conversation,

The OFFICIAL REFEREE said: Defendant being away you have closed your case. There is no evidence on the counter-claim, and I shall go on with the case. I am not satisfied with the reasons for an adjournment. You are quite at liberty to go to the Court at the earliest possible time if you like, and I will withhold my award if you ask.

Mr. SMITH: Very well, I will do that.

Judgment was given for the plaintiffs.

COMPANIES' MEETINGS.

The Old Atlantic Cables and the Newfoundland Land Company.

The ordinary general meeting of the Newfoundland Land Company (Limited) was held on December 5 at Winchester House, Old Broad-street, E.C., followed by an extraordinary general meeting.

Mr. HENRY WEAVER, managing director of the Anglo-American Telegraph Company, occupied the chair.

The SECRETARY (Mr. T. H. Wells) having read the notice convening the meeting and the minutes of the last meeting,

The CHAIRMAN briefly proposed the adoption of the report and accounts to the 31st December, 1886, intimating that the important business before

Digitized by Google

the meeting on that occasion had to be dealt with at the extraordinary meeting which had been called.

Sir JAMES ANDERSON seconded the motion, which was adopted.

The CHAIRMAN afterwards proposed the re-election as Director of Mr. Cyrus Field.

Mr. GEORGE HEIRON and Mr. WM. ABBOTT suggested that this motion should be deferred until the close of the extraordinary meeting, which was agreed to.

The extraordinary meeting was then held.

The CHAIRMAN: The important business of this meeting really is to ascertain how far the affairs of the Company are for the future to be carried on. As you are aware, the present Board agreed that they would remain in office until they had obtained the grants of land applied for. We have now obtained all the grants we are likely to obtain, because the grants which had been applied for in addition to those received have already been allotted, and therefore we cannot have them. We have now obtained a total of 39,002 acres, and there are a further 21,998 acres which may be applied for by the Company. I went on a former occasion into the history of this concern, and I think that I had better repeat what I told you at that time. The land upon which this Company was incorporated formerly belonged to the Newfoundland Telegraph Company. That company was incorporated by charter from the Newfoundland Government about the year 1856, and it was incorporated for the purpose of laying a line or lines of submarine cable between Newfoundland and this country, and to erect a system of telegraphs on the island of Newfoundland. The Government of the Colony while granting this charter did not give any subsidy to the Company, but gave them the selection of 100 square miles of land to work in any way they might think desirable. There was a clause in the charter of the Newfoundland Telegraph Company giving them the power of fusing their undertaking into the company which actually laid the Atlantic cables, and which you are aware was the Anglo-American Company, as the successors of the Atlantic Company. Now, at the time of this fusion in 1873 it was found at the last moment that the Anglo-American Company had no power whatever to hold land, and the consequence was that this Company was incorporated for the purpose of taking over the land belonging to the Newfoundland Telegraph Company, and to dispose of it or work it in any way that seemed most desirable. That was the history of the commencement of this Company, and the shareholders of the Newfoundland Telegraph Company received for every share which they held in that company a land share, so that really no money whatever was subscribed. They received a share of the Land Company, in addition to the stock of the Anglo-American Company which they got for their undertaking. There was a certain sum of money which belonged to the Newfoundland Telegraph Company, which was taken over by the Land Company, who became responsible for the debts of the Telegraph Company, the balance to be used in any way that appeared most desirable to the Board. The Directors of the Newfoundland Telegraph Company were asked and urged to accept seats at this Board, and as no one else was willing to accept them we were obliged to take the place, and the first thing we did was to consider what we were going to do with the land. What we really did do was this—we fitted out two expeditions. I think they went out in 1874 and 1875. They went to Newfoundland to see whether in reality there was anything to be done with the land, and when they came back their reports were so unfavourable that the Directors decided that they had better not ask for the money which was necessary to work the land which the Company had, and the Board returned the money which they had already raised by preference shares—something like £4,000. At that time, and at several meetings since, I have recommended the shareholders to wind up the Company, for I really did not see that anything was to be got out of it in any way; but at the wish and request of the shareholders we were desired to retain our seats, and, in fact, wait until something turned up. That was really the whole thing. On the last occasion we proposed that the Company should be wound up, but the shareholders asked us to wait until the land had been allotted. We consented to that, and now the land has been allotted—at least as much as we can get—and we now ask you what is the next thing to be done. We have told you on several occasions that we are not disposed to do anything else ourselves. We understand nothing about land or mining. We are simply telegraph men, and we do not wish to go outside our functions. We therefore asked you in the report either to appoint a committee to elect new Directors or to wind up the Company. I find now, looking at the proxies which the shareholders have sent in, that a very large majority are in favour of a committee being appointed for the purpose of electing a new Board—a majority, in fact, of 5,231 shares, or rather more than that, because we have had some come in this morning. The majority, I find, is 6,260 shares in favour of a committee being appointed to elect a new Board. We have not the slightest objection to that course being taken, and we shall only be too happy if a committee is appointed to elect new Directors.

Sir JAMES ANDERSON: I should like to add a few remarks by way of showing that we have left no stone unturned to find out whether anything could be done for this Company. Two gentlemen were recommended to us by the School of Mines—geologists—and they gave us a report, which is accessible to any shareholders who wish to see it. They found out nothing that would induce us to put our money into the concern, or that would justify us in recommending you to do so. Some personal friends of mine engaged in the metal trade in London, who spend a great deal of money in looking after deposits of copper which seem to offer favourable conditions of working, expended at least £25,000 in explorations on our property, and had they got anything worth working we should have very likely come to you with a new Board who understand the business, and have asked you to risk something on that venture; but they lost their money. We then had a fish scheme brought before us, and when I was in Newfoundland myself I learned a great deal about what that sort of thing was. I felt that I would not put a shilling of money into it, and after Mr. Bompas, Mr. Weaver and myself examined the matter carefully, we decided not to touch it. From that time we have seen nothing and known nothing about Newfoundland to encourage you to put your money there or to go there.

Mr. WM. ABBOTT said that the shareholders must feel very much indebted to the Directors for having remained on the Board so long. They had said very properly that they were telegraph men; and if men would only keep to what they understood a great deal of public money that was now lost would be saved. Reference had been made by Sir James Anderson to the visit of geologists to the Company's property, and to their finding nothing; but the fact remained that in Newfoundland there were some of the richest copper deposits known. There was now a rise in the price of copper, and the position of affairs was therefore totally changed to what was the case some little time ago. He was recently at Swansea, where he saw large smelting works, and there were immense heaps of copper ore there which he was informed had come from Newfoundland. It was quite a mistake to imagine that there was nothing in Newfoundland but codfish. He believed the place was rich in minerals, and therefore he did not wish to see the Company wound up. At the same time he thought that the Directors had taken a wise course in appealing to the shareholders as to what steps should be taken in regard to the future of the Company, and, as the Chairman had said, a majority had answered in favour of appointing a committee to select a new Board. They had now 39,000 acres allotted to them out of their 100 square miles, and he would be glad to hear what difficulties the Newfoundland Government placed in the way of allotting to the Company the balance. He did not think that the Government of the Colony had kept good faith with them, because whenever it was desired to have a free grant of land allotted to them it appeared that someone had stepped in before them. He thought that what the meeting had to do that day was to follow the advice of the Directors and appoint a committee with the view of picking out three or four gentlemen who would take the place of the present Directors. The Company was not entirely penniless, for he saw that they had £320, and there were also 6,774 shares unissued. It would be said that those shares were not worth much—and perhaps not; but he would suggest that when a new company was formed the shareholders should be offered those shares at 6s. each. That would produce over £2,000, which would keep the thing going a little longer. Their position, therefore, was not entirely hopeless. It might be said would the shareholders take those shares at 6s.? Well, if the Directors were in a position to offer them at 5s. he would at once agree to take the lot at that figure, and see whether they could not develop the 39,000 acres of land which had been allotted to them, and whether they could not bring some influence to bear on the Newfoundland Government to grant them the balance of the land to which they were entitled.

The CHAIRMAN asked whether Mr. Abbott knew of any gentlemen who were willing to form the committee and to accept the liberal offer he had made to purchase the shares.

Mr. ABBOTT replied that he did, but that he would be glad to be given a few days to consider the matter. He would suggest Mr. George Heiron; and Mr. Arthur Baker had asked him (the speaker) to put his name on the committee. He had also just been informed that Mr. Greenip would go on. He thought that the shareholders had every reason to be much obliged to the Directors for what they had done.

Mr. HEIRON acquiesced in Mr. Abbott's remarks, and said that he had some knowledge of Newfoundland from surveys which had been taken there, and the parties making those surveys had spoken in very different language of the prospects of mining compared with what had been stated by the gentlemen referred to by Sir James Anderson. It was to be remembered that until o e went into the earth, one could not tell what the prospect in connection with mining would be. If the shareholders wound up the Company they would not get a farthing back. The annoying fact was that the Company were only to get 39,000 acres instead of 64,000, which the Newfoundland Government had promised them.

The CHAIRMAN: Oh no; that is not so. You will get the balance, but you must apply for it. You have a perfect right to apply that the balance should be allotted to you.

Sir JAMES ANDERSON: The great point is to send out the right people to select the right land.

Mr. HEIRON took it for granted that every assistance would be given by the office.

Sir JAMES ANDERSON replied that every possible information would be given.

Mr. DAVIDSON inquired whether there was still unallotted by the Newfoundland Government a sufficient quantity of land so as to give to the Company what they were entitled to.

Sir JAMES ANDERSON: Oh, yes, many times over.

The CHAIRMAN said that he thought the best course for him would be to propose the first resolution mentioned in the report, which was as follows:—"That a committee be appointed for the purpose of selecting a new Board of Directors, who will undertake the future conduct of the business of the Company."

Sir JAMES ANDERSON seconded the motion, which was carried unanimously.

The CHAIRMAN then proposed the appointment of a committee consisting of Mr. Geo. Heiron, Mr. Arthur Baker, and Mr. W. M. Greenip.

Sir JAMES ANDERSON seconded the motion, which was unanimously agreed to.

Two or three SHAREHOLDERS urged Mr. Abbott to join the committee, but that gentleman said he would prefer not to accede to the request, because his time was occupied in other ways.

The CHAIRMAN said that he had consulted Mr. Bompas as to the re-election of Mr. Cyrus Field, but that question need not come before the

Digitized by Google

meeting, because Mr. Field had agreed to do whatever the other Directors did, and they were going to retire. Sir James Anderson and himself would be glad to appoint any day to see the committee.

Sir JAMES ANDERSON observed that whatever committee was appointed the Company would go on languishing unless they arranged to find some money.

Mr. HEIRON said that that would be a matter which would be gone into by the committee in conference with the new Board.

Mr. ABBOTT proposed a hearty vote of thanks to the Directors for what they had done. It had been a very thankless office for them, for they had been fighting against circumstances. They had brought their influence to bear on the Newfoundland Government, with results of which the shareholders already knew.

Mr. HEIRON seconded the motion, which was carried unanimously.

The CHAIRMAN, in acknowledging the vote, said they were much obliged to the shareholders. After all the Directors had not done much, but they had done all they could to obtain the land and they had succeeded to the extent mentioned. There was one fact certain, that whatever their work had been, the Directors had done for the shareholders gratuitously for fourteen years.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The directors of this company on Wednesday declared an interim dividend of 3s. per share, being at the rate of 6 per cent. per annum, free of income-tax, for the quarter ended 30th September, and payable on the 23rd inst. The books of the company will be closed from the 16th to the 22nd inst., both days inclusive.—The traffic receipts of this company for the week ended Dec. 2nd amounted to £4,817.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of November was 3,343, estimated to produce £3,000, against 3,077 messages, producing £2,580, in the corresponding month of last year. The traffic receipts for the month of August, estimated at £2,250, realised £2,280.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts for the month of November are £2,115, against £1,876 in the corresponding period of last year.

EASTERN TELEGRAPH COMPANY.—This company announced the payment on the 4th January next of interest at the rate of 3s. per share on the preference shares of the company, less income-tax, for the quarter ending 31st December, 1887; and on the same day an interim dividend will be paid of 2s. 6d. per share in respect of profit for the quarter ended 30th September, 1887, on the ordinary shares of the company, free of income-tax. The company's register of the transfers will be closed from the 6th to the 13th January, both days inclusive.—The traffic receipts of this company for the month of November amounted to £53,454, and to £50,817 in the corresponding period of 1886, being an increase of £2,637.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—This company notify that the coupon on their Five per Cent. Australian Government Subsidy Debentures, due on the 1st January next, will be paid after that date at Messrs. Barclay, Bevan and Company's Bank, 54, Lombard-street, E.C. Coupons must be left three clear days for examination.—The directors have declared an interim dividend for the quarter ended 30th September last of 2s. 6d. per share.—The traffic receipts of the company for the month of November amounted to £39,000, and to £36,739 in the corresponding period of 1886. Increase, £2,261.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for November amounted to £22,000; from 1st January to 30th November they amounted to £242,880; while for the corresponding months of 1886 and 1885 they were £239,000 and £264,440 respectively.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY. — The traffic receipts of this company for the week ended December 2nd were £3,870, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended 30th November were £4,225.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 30th November are £2,627, as compared with £2,357 in the corresponding period of 1886.

SOUTH METROPOLITAN ELECTRIC SUPPLY COMPANY (LIMITED).—This company was registered on the 26th ult., with a capital of £250,000 in £10 shares, "to produce electric, magnetic, or other force, and to supply the same for light and heat."

THE MAXIM-WESTON ELECTRIC COMPANY (LIMITED).—The following circular has been issued to the shareholders of the above company:—"Dear Sirs: At the request of a number of influential shareholders, the directors are pleased to be in a position to inform you that their business during the past year has been in excess of any previous year, notwithstanding the universal depression existing in nearly every branch of trade, and the very heavy opposition they have had to contend against. The complete installations fitted up during the present year, including steam or other motor power and all requisites, amount, to the 1st of this month, to about 200 arc lamps of 2,000 candle-power each, and about 5,000 incandescent lamps of 20 candle-power each. We have also during the past year had an increase in our usual orders, and the result to date is therefore satisfactory. All installations fitted up to date have given satisfaction, and the company have succeeded in securing orders in the districts where these have been fitted up, at even higher prices than those quoted by other companies. During this year the company have been successful in opening up a new branch, having secured the lighting of several large ocean-going steamers, which have been lighted successfully; and the company are promised the lighting of twelve new steamers, as soon as these vessels are built. The directors are pleased to be able to add that they have secured a new dynamo and lamp, by means of which they will be able to apply arc installations upon a scale for which there is infinitely greater requirement than heretofore. I refer to what is known as the 'Watt' system, comprising a dynamo and arc lamp of 150 candle-power. These are produceable at a reduction of 50 per cent. under the Weston system. The dynamo will also be suitable for Admiralty requirements, and we are in hopes of securing a trial order for several of these dynamos. We will be able to supply dynamos capable of running from 60 up to 1,000 lamps each machine, at varying speeds of from 200 up to 1,000 revolutions per minute. The price at which we will be in a position shortly to supply these machines will be less than that of any other dynamo maker in the market. The company are already in receipt of inquiries for the dynamo from all parts of the world, and have had the opinion of several of the leading experts in the country, all of whom are agreed as to the mechanical and electrical efficiency and suitability of the machine. The directors may congratulate the proprietors on the extent and suitability of their new factory, having already found it necessary largely to increase their fixed plant, and this fact, with the amount expended during the past year for experiments in connection with the dynamo named, has decided the directors to offer to the shareholders the balance of the 50,000 shares left in their hands to issue 'as and when required' at 5s. each, par value. The directors are happy to report the steady growth of business, the prospects of the company being now better than at any past period. The principal difficulties they have hitherto had to contend with have been their inability to supply the arc system in a distributed form, and there is no doubt that the small arc lamp now perfected will enable the electric light to be applied to the cities and towns in Britain and Europe generally on a large scale (as is now the case in America) upon economical terms. The directors hope they will be supported by the shareholders in the matter of capital in applying for these shares, after having, during several years of arduous labour, succeeded in bringing the company to a first position among the electric lighting companies in Europe, with only about 10 per cent. of the capital at the disposal of competing companies. In the event of the shares being over-applied for, the shares will be allotted *pro rata* to the shareholders.—Yours, &c.—HUGH WATT, M.P., Chairman."

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 500.—Vol. XX. FRIDAY, DECEMBER 16, 1887. Price 4d.

NOTES.

It would be difficult to say when the idea of rotating the field of a dynamo in one direction and the armature in the other first dawned upon the mind of the dynamo constructor. Probably Wheatstone and Gramme, and Varley and Wild, and Ladd and Siemens each contemplated the idea—and came to the conclusion that the game was not worth the candle. In another column will be found a description of a machine of this type designed by Lieut. Patten, of the United States Army. It will probably be conceded that the details of the design present points of merit, but it must still be doubtful whether the device ensures any real economical advantage.

The Corporation of Bradford are to be congratulated on the sensible and moderate tone which is so far characterising their dealing with the electric light question. Their determination to start a small central station for the public supply of electricity is the more noteworthy as they already own the local gasworks. It is a little unfortunate perhaps that the Gas Committee was unable to come to terms with Messrs. Schmidt, Douglas and Co., who for some time past have been supplying a certain number of lamps from their station at Kirkgate; but the arguments raised on either side are of a purely local character, and afford no data for the opinion of those not immediately on the spot. We trust, however, that the local company will be enabled to proceed with their own undertaking side by side with the forthcoming scheme of the Corporation.

Mr. Alderman Priestman's electrical science appears only to need amendment in one particular. His preference for a low tension over a high tension distribution, on the ground that the former affords absolute immunity from fire, while the latter does not, is scarcely in accord with generally accepted views.

Notwithstanding the labours of Clerk-Maxwell and Sir William Thomson it must be supposed that some time will yet elapse before electricians are able familiarly to discuss magnetic and electric induction through space in terms of the affectation of the ether. When that time arrives, however, we take it that the paper by Messrs. Michelson and Morley, in the current number of the *Phil. Mag.*, will be as interesting to electricians as it is now to the student of general physics. The writers describe a research undertaken in order to examine the question whether or not the assumption which is usually made that the ether (as a whole) is at rest in space would stand the test of experiment. The assumption is one which seems to an ordinary intelligence a very reasonable one, and, moreover, it has been shown by Fresnel that in order to complete the explanation of the aberration of light according to the undulatory theory as at present understood such an assumption is absolutely necessary. Nevertheless, the experimental evidence obtained by the writers referred completely upsets this view, and tends to show that upon or near the surface of the earth the ether moves onward with the same velocity as the earth in its orbit. It must be admitted that the result is an extraordinary one, and difficult of interpretation; for if the ether in the neighbourhood of the earth is carried onward with the same velocity as the earth itself, it would appear that something corresponding to a shearing stress would be set up in the medium. This makes things more complicated than ever.

Telephony has hitherto been a plant of slow growth in the West of England. The "Three-Towns," as they call themselves, of Plymouth, Devonport, and Stonehouse, embrace a population considerably exceeding 150,000, and yet a local journal finds it a subject for congratulation that there are now "no less than 202 subscribers" on the local telephone exchange. This stagnation has, in part, been the result of a prolonged dispute between the Post Office and the Telephone Company, in which, whatever may have been the merits of the original quarrel, the Post Office has got so much the worst of it that its own exchange, started in 1881, now drags out a lingering existence on a list of 12 subscribers! The Western Counties and South Wales Telephone Company commenced operations in 1884, three years later than the Post Office, and adopted a broad and liberal policy towards their subscribers, which is, in fact, characteristic of this company. The chief cause of the lack of success of the Post Office Exchange arose from the persistent and (to an outsider) the utterly unaccountable refusal of the Department to open telephonic communication between Plymouth and Devonport. It would be really interesting to know for what possible reason the Post Office found itself unable to accede to the repeated requests for this extension. That the improvement was, nevertheless, sooner or later, inevitable must have been obvious to all concerned However, we take it that should the Department ever undertake a more extended responsibility for the telephonic communication of this country, they would see their way to adopt a wiser and more liberal policy than that which has characterised their conduct at Plymouth.

THE recent rise in the price of United Telephone Stock has been due to rumours of an approaching re-amalgamation of the provincial systems with the parent company.

Two or three suggestive articles have lately appeared in the *St. James's Gazette* on "Telephone Rates and Renters," chiefly directed against the rates which prevail in the metropolis. The writer's arguments and figures are not always convincing; but there is one point on which we have ourselves commented in these pages with regard to the London telephone service, and which the *St. James's* puts with some force, namely, that the area being so vast it might be cut up into districts, with a lower initial charge and extra fee when the renter wishes to go beyond the one in which he is located. A division of this kind would not be attended by serious difficulty, inasmuch as the experience of the United Telephone Company shows already that a considerable percentage of the total number of communications takes place through wires connected with the same switch room, of which there are now no less than twenty-four in different parts of the metropolis.

THE writer enforces his argument for reduction of telephone rents in London by reference to other towns, notably in Scotland. But the rent in Paisley is the same—namely, £10—as in Aberdeen; yet the proportion of renters to population is more than two-and-a-half times greater in the latter than in the first-named place. Besides, look at America, where the rents are universally higher and the users far more numerous than anywhere else. There must be other reasons to account for the diversity on which the writer has built up his theory. One of these reasons—in London, at all events—is the existence of a local system of Post Office Telegraphs, a system which is certainly largely patronised by the inhabitants, the increase of telegrams in the metropolitan area under the sixpenny rate being far in excess of the normal increase for the rest of the country. It is, perhaps, neither expedient nor possible for the United Company to extinguish this local telegraph traffic by telephony.

So long as there is a good service the public will not care much whether it is performed by a telephone company or the Post Office. There is one passage, however, in the *St. James's* Saturday's article which indicates a gradual obliteration of the distinction between telephony and telegraphy. When we remember that each one of the provincial telephone companies provides the majority of its subscribers with a more or less extensive system of trunk lines, by which for a small extra charge they may communicate not only with the towns in the immediate neighbourhood, but also in many cases with places distant 100 miles and more, it is apparent that the competition of the telephone with the telegraph is already of a formidable character. We have here an explanation of the loss, or at all events relative slowness of gain, which the Post Office Telegraphs are manifestly sustaining. And, perhaps, it will now be admitted that they were technically, as well as commercially, right who maintained from the first that a telephone system is a telegraph system. No wonder the Post Office regard this extension of the telephone with misgivings, and perhaps with alarm.

THE paper read by Dr. Shettle at the Physical Society on Saturday last (of which some account will be found in another column) contained a compendium of the views of the learned Doctor on the subject of a "supposed new force." Inasmuch as the experiments which have led Dr. Shettle to the conclusion which he now holds were originally set forth in the columns of this journal, it may be as well if we state very briefly what is at present our own view of the question. It is impossible to deny that these experiments have been conducted with conscientious accuracy and with very considerable manipulative skill, and it is therefore to ourselves a matter of sincere regret that we are obliged to arrive at the conclusion that Dr. Shettle has overlooked a very simple explanation which lies at the bottom of the phenomenon which he has been so diligently examining, and which, if recognised earlier, would probably have led him to the conclusion that there was, after all, little or nothing to be learnt by an elaborate course of detailed experiments of this nature.

THE whole argument can be put in a nutshell. Dr. Shettle takes a sphere of some insulating material, he winds it round with copper wire, and suspends it very delicately in front of the pole of an electro magnet. In different experiments the winding is done in various and elaborate forms, but—and here lies the whole secret—*the ends of the wire are always joined so as to form a closed circuit.* Now, when the current is switched on to the electro magnet Dr. Shettle observes a movement in the suspended sphere, and it is the nature and extent of these movements which he has been diligently investigating. But it is very difficult to see where the necessity for a "new force" comes in. The motion takes place during the incipient stage, while the magnetisation is growing, and therefore the closed circuit suspended in front of the pole of the magnet is cut by an increasing number of lines of force, with the necessary consequence that an induced current traverses the wire, and then the reaction of the resultant magnetic field of the coil upon that of the magnet itself determines a deflection or rotation of the sphere.

A MEMBER of the Physical Society writes to us on the same subject. The following is a portion of his remarks:—"Some of Dr. Shettle's spheres were solid, and others formed of a large quantity of copper wire wound on small wooden spheres in a fearful and wonderful manner; but it is quite clear that the manner of winding would have no effect upon the general character of the action. The method of winding was intended to illustrate some theories of Dr. Shettle's, which, we fear, were quite outside the comprehension of the members of the society, who for the most part labour under the disadvantage of having undergone a scientific training, which would naturally unfit them for following the author in his airy flights through the regions of imagination, not of the nature called scientific, but of a higher and more transcendental kind, untrammelled by anything so earthly as facts, and which explain to his more unfettered mind all the physical pro-

Digitized by Google

blems of the universe, from the movement of a planet in its orbit to the ascent of sap in a dandelion."

Some surprise appears to have been occasioned by the line we have taken on the Fire Office Rules relating to electric lighting. We beg to state that the line in question is a very innocent one, and leads directly to a quite inoffensive termination—namely, the establishment and enforcement of one set of rules which shall deserve and command general acceptance. One set already does exist, and has not been seriously objected to in any public manner that we are aware of. No doubt the Council has excellent reasons for the course it now appears to have been following; but it can have none for complaining that technical journals, failing authoritative information, have adopted a line not exactly identical with that pursued by the Society.

When an alternating current is passed through a voltmeter it is obvious that, if the periodic time be gradually lengthened, we should at length arrive at a point where the liberation of gas would commence. The observation of the value of this period under given conditions of temperature and pressure, for different electrolytes, would almost certainly lead to results of some importance in the theory of electrolysis. Very probably this question has already received the attention of the members of the Electrolysis Committee of the British Association, but if not, we venture respectfully to commend it to their consideration.

The question has also a practical bearing, for it is a fact well known to many users of alternating current machines that a liberation of the mixed gases sometimes takes place when a water resistance is traversed by an alternating current. The action, moreover, takes place equally at both electrodes, and has been observed under a periodic time at least as small as $\frac{1}{60}$th sec. (3,600 alternations per minute). The result is rendered more obscure by the fact that it is by no means constantly apparent, even under what appear to be the same conditions. We believe, however, that there is some reason to suppose that it is dependent on the E.M.F. as well as the rate of alternation.

Since writing the above Note we learn that there is actually in existence—and in fact in use on a small scale—an alternating current meter based upon electrolytic decomposition. We understand that the instrument has every prospect of being a highly successful one, but at present it is not wished to make public the precise method of action.

According to Mr. J. M. Cattel, psychologists can now by the aid of electricity determine the time taken up by our mental processes, or "The Time it takes to Think," which is the title of his article on this subject in the current number of the *Nineteenth Century*. By the well-known device of causing a tuning-fork vibrating at the rate of, say, five hundred times a second to record its movements in a wavy line on a rapidly revolving drum, each undulation may be made long enough to be divided into twenty equal parts, and thus time can be measured to the ten-thousandth part of a second. Adapting an electrical current under the experimenter's control to this device the time elapsing between a sense-stimulus and the identification of it can be measured with great exactness. Thirty-five years ago Du Bois-Reymond succeeded in proving that this interval was less than ·001 second. But that this is timing "thought" we take leave to doubt; in most of the instances given it is the interval between perception and reaction, simple or complex, that is measured. But the experiments do seem to prove that thought is a comparatively slow process, and that to say "as quick as thought" is not saying much for the quickness. Electricity is infinitely quicker, and has the further merit of actually going whither we list, while our thought is only thinking about going.

Offenburg.—A local company has been formed at Offenburg for the supply of electric light.

A German Magnetic Observatory.—It is intended to establish a magnetic observatory in the neighbourhood of the existing astronomical observatory near Potsdam.

The West Indian Cables.—Telegraphic communication with the Island of Antigua, which has recently been interrupted, is now restored. The cable between Trinidad and Demerara is still interrupted.

"The Management of Accumulators."—We have received from Messrs. Whittaker and Co. a copy of the third edition, revised and enlarged, of Sir David Salomons' work on "The Management of Accumulators."

Utilisation of the Treadmill.—According to the *Daily News* the prison authorities have decided to consult the electrical engineering profession as to the possibility of utilising the treadmill power which at present is allowed to waste.

Award.—We are glad to learn that Messrs. Woodhouse and Rawson (Limited), of 11, Queen Victoria-street, have been awarded the First Order of Merit for their exhibition of electrical fittings and appliances at the Exhibition now being held at Adelaide.

The German Cables.—A Berlin telegram of Tuesday last states that the Bill for the purchase, by the State, of the present telegraph cables between Germany and England will be brought forward in a few days. The expense of the transfer is reckoned at about seven millions of marks. Immediately after the nationalisation the Anglo-German tariff will be considerably reduced.

Elberfeld.—The installation undertaken by the Municipality of this town commenced working a few days since. It has been carried out on the Edison three-wire system, and at present does not absorb more than 120 horse-power. Aron meters are in use, and a special form of this instrument has been designed to meet those cases in which a single installation is connected with both sides of the main circuit.

Country House Lighting.—We learn that Benacre Hall has recently been supplied with electric light, the installation having been carried out by Messrs. J. Edmundson and Co. The dynamo is driven by an engine of eight horse-power nominal, capable of working a hundred 16 candle-power lamps. An accumulator capable of supplying seventy-five lamps of 16 candle-power for nine or ten hours has also been supplied.

Leamington.—We are glad to learn that the Leamington installation is making steady progress, and that up to the present time everything continues to work satisfactorily. We make this announcement in view of the fact that a rumour to the effect

Digitized by Google

that difficulties had arisen with the Corporation has been in circulation, but on inquiry we are assured that this statement is entirely without foundation, and that all is going on well.

The Atlantic Cable "Pool."—Action in France.—A Paris telegram states that the action brought by the Anglo-American Telegraph Company against the Transatlantic Cable Company for breaking away from the other companies in the "pool" came on before the Tribunal of Commerce on Tuesday. The case, says the *Central News*, is an important one, as testing the binding nature of the agreement, and on the French side it was contended that the whole arrangement was an illegal one. After hearing the arguments on both sides, it was announced that judgment would be given on the 17th inst.

Telephone versus Speaking Tubes.—Telephones are now coming into use as a substitute for speaking tubes in large buildings. The Equitable Telephone Association (Limited) has just completed an installation of six instruments at 27, London-wall, whereby all the different floors of the warehouse are put in direct communication with one another, and with the general and private offices. The same company has at present in hand a similar installation, with 27 telephones, in the new warehouse and offices of the Co-operative Wholesale Society (Limited), Leman-street, Whitechapel.

Weston-super-Mare Town Lighting.—The Weston-super-Mare Local Board invite tenders for lighting their district with electric light. Tenders to state price for lighting, providing, fixing, and keeping in thorough order and repair all wires, posts, &c., connected with the lighting of sixty lights, 1,200 candle-power, averaging six hours per day, ditto seven hours, ditto eight hours, at per light per annum, for three, five, and seven years respectively, also (same number of lamps and candle-power) per hour, for the respective periods of three, five, and seven years. Sealed tenders to be sent to Mr. W. Smith, clerk, Town Hall, Weston-super-Mare, endorsed "Tender for Lighting," by 19th inst.

Fire at Messrs. Johnson and Phillips's Factory.—We regret to record that early on Wednesday morning a fire, which rapidly assumed serious proportions, broke out in Messrs. Johnson and Phillips's factory at Victoria-road, Charlton. The factory consists of a number of detached buildings, and by the exertions of the fire brigade the damage was confined to the workshop in which it broke out; but this building, with the valuable machinery which it contained, was almost completely destroyed. Messrs. Johnson and Phillips request us to make known that the conduct of their business has not been in any way interfered with by this accident, and they will be enabled to execute orders with as much promptitude as before.

Lighting of the Royal Albert Hall.—The lighting of the Albert Hall has hitherto been effected solely by means of a double row of gas jets placed around the base of the dome. As many of our readers will be aware, these jets were lighted by means of a large induction coil apparatus, supplied, if we mistake not, by Messrs. Apps. It was recently decided, however, to introduce electric lighting for the lower portion of the hall, and the three tiers of private boxes have been encircled with incandescent lamps; but it was then found that the orchestra became so dark by comparison that it has been decided to place additional lamps depending from the ceiling over the platform. The work is being carried out by the Anglo-American Brush Company.

The Fouling of Ships.—At the Royal United Service Institution Mr. C. F. Henwood recently read a paper on a matter of vast importance, both in relation to our ships of war and the mercantile marine—namely, the corrosion and fouling of the bottoms of iron and steel ships. Mr. Henwood advocated the use of zinc as a sheathing, which, even as hitherto imperfectly applied, tends to preserve the iron or steel from corrosion in sea water, and in certain cases from fouling. He "considered that it might be fairly and reasonably assumed that zinc-sheathing, if applied so that the electro-positive zinc was in contact with the electro-negative iron or steel, the zinc would be perpetually dissolving away in an oxide, and carry with it the barnacles and other zoophytes, leaving a clean surface."

The Phonograph.—The announcement of the fact that Edison has lately perfected his phonograph, has naturally led to a host of rival inventions. Of these, the most noteworthy are those of Prof. Graham Bell and of Mr. Berliner. All these are purely mechanical appliances; but in the phonograph of Mr. R. M. Hunter the aid of electricity is secured. Mr. Hunter takes a trace on a sheet of specially prepared carbon paper, and the instrument repeats the words through a telephone receiver, by means which will readily suggest themselves to the electrician. It is thus inferior to the Edison apparatus in the loudness with which the tones are reproduced.—We have been interested to learn that Colonel Gouraud, who is a personal friend of Edison's, will in a few weeks enter into regular phonographic correspondence with him. The arrival in this country of Edison's first phonogram will naturally be looked for with considerable interest.

Prize Essay.—We learn from *L'Elettricita* that the Italian Society for the Advancement of Electrical Science and its Practical Applications has offered a gold medal of the value of about £30 for the best memoir on electro-magnets, from the point of view of affording practical guidance in determining the best forms and dimensions for the field-magnets of a dynamo. The memoirs are to be written in French or Italian, and to be sent to the Executive Committee before the 30th October, 1888, each memoir to be inscribed with a motto and accompanied by a sealed envelope bearing the same motto on the exterior, and containing the author's name and address. The competition is to be open to all comers, and the society is to have the right of printing an edition of 1,000 copies of the successful memoir, of which 100 will be sent to the author, who will retain the right of issuing further editions. The unsuccessful memoirs will be retained in the possession of the society.

Electricity versus Gas.—A firm in Brussels which has been using the electric light for the last twelve months as a substitute for gas in their spinning mills shows the following comparative statement of cost in the two cases:—

Gas (previous year).

	£	s.	d.
360 burners, 123 litres each, at 18 centimes per cubic metre, cost per hour 7·97fr. (6s. 3d.).			
857 hours per annum, at 6s. 3d. per hour	£273	3	4
Maintenance	24	0	0
	£297	3	4

Electricity.

	£	s.	d.
Carbons, consumption per lamp hour = 44 centimes			
36 lamps for 857 hours = 1,357·5fr.	£54	6	0
Interest and depreciation, 12 per cent. upon 15,000fr. = 1,800fr.	72	0	0
Maintenance, &c.	14	0	0
Coal	10	1	0
Extra coal for warming the building	8	1	0
	£158	8	0

Balance in favour of electricity, £138. 15s. 4d.

The Government and the Submarine Telegraph.—A Dover correspondent of *The Times* states that, in anticipation of the taking over of the submarine telegraph, the postal authorities are actively engaged in perfecting and improving the means of communication between the central office in London and the shore end of the cable which crosses the Straits of Dover. The plans for the new arrangements will occupy the attention of the staff throughout the year 1888, at the end of which period the cable will be taken over. During the last few winters some very serious delays have taken place in the transmission of messages owing to the damage occasioned to the wires during severe weather. With a view to prevent the occurrence of these delays as far as possible, the postal authorities are having insulated wires placed in tubes underground at all notably weak points on the line between Dover and London. The submarine wires, which are connected with the cable at St. Margaret's Bay, and which have hitherto been run into Dover from the cliffs on poles, have all been replaced in tubes in this way, and carried as far as Dover central post office, through which Continental messages will be transmitted. Provision has been made for increase of business by the laying down of several additional wires.

Theatre Lighting.—At a recent meeting of the Royal Institute of British Architects a paper was read by Mr. Ralph Nevill, F.S.A., on "The Auditorium of a Theatre." The following are Mr. Nevill's views as to lighting:—"Lighting ought to be regarded by the manager as a potent means of inspiriting an audience. It might be accepted that the electric light would be used, but nevertheless provision must be made for gas. To be successful artistically the light must be various. In the event of fire the electric light would be extinguished; the gas sunlight ought therefore never to be put out, but turned low during the performance, and turned up full between the acts, the electric light being turned quite out in the first case, so that the eye was entirely drawn to the stage. The front of the circles was the natural place for electric lights. The electric light rendered no great provision of fresh air necessary during a performance. It would, however, be always requisite to provide an exit for impure air; and as long as gas was used behind the scenes, there must be sufficient ventilation to take away the enormous and dangerous heat at the top, without creating a draught to the stage. At the present moment the question of fire risks was that which was of most interest in connection with theatres, and after deprecating more than a certain degree of legislation and State interference, the author expressed his belief that in London, in a well-regulated theatre, fire risks were of the slightest."

Physical Society of Glasgow University.—The Gray-Milne Seismograph.—A meeting of the above society was held on the 9th inst. in Mr. James White's Scientific Instrument Factory, at Glasgow, Mr. Magnus Maclean, president, in the chair. Mr. Thomas Gray exhibited and described an improved form of the Gray-Milne Seismograph. This is an apparatus designed to record the various motions of the earth at a point on its surface during the transit of an earthquake, together with the time at which the motions take place, and their period. The motions are recorded in ink on a band of paper in the form of three components, one vertical and two horizontal, at right angles to each other. The band of paper is kept continually moving forward at a very slow rate, and marks are made upon it at equal intervals of time by means of a pen actuated by a separate clock. An automatic apparatus is provided which, at the time of an earthquake, greatly increases the speed of the paper feed, and thus allows the different motions of the earth to be clearly separated. The same automatic apparatus also brings into action mechanism for recording much shorter intervals of time on the paper during its transition from slow to quick speed. After a short interval the speed is changed back to slow, and the automatic apparatus readjusted by the clockwork itself. The apparatus is capable of recording any number of successive earthquakes which may take place during a week without adjustment by the observer. At the same meeting Mr. T. A. B. Carver explained a quick method of photography, which has also the advantage of allowing prints to be taken by gaslight. He illustrated the method by photographing the seismograph, the negative being taken by magnesium light, and the prints by gaslight.

Technical Education Conference.—On Wednesday evening a conference on technical education was held in the Royal Victoria Hall, Waterloo Bridge-road, for the purpose of enabling the employers and workmen of the neighbourhood to meet and discuss the subject from their several points of view, especially with regard to probable legislation. Sir Henry Doulton presided, and letters of regret for non-attendance were read by Mr. Charles Morley from the Marquis of Ripon, Sir Frederick Abel, the Dean of Westminster, the Bishop of London, Sir Ughtred Kay-Shuttleworth, Prof. Seeley, Mr. George Howell, M.P., Mr. Mundella, M.P., and others. The Chairman said that the technical education movement was now absorbing the attention of the English people. John Bull had been sound asleep, but he had woke up with a start. England must maintain her industrial supremacy, which was being challenged on all hands. All that the Government could do, all that great corporations could do, and all that individual energy could do, must be done. A better kind of manual teaching was undoubtedly required in our primary schools.—Mr. Bockett (a working man) then read a paper on the question before the meeting. From the recent Parliamentary Bills, he said, it was clear that the legislators on both sides of the House only felt strong enough to tinker with the subject. He thought genuine trade guilds should be formed in order to start technical schools, to be managed by a mixed committee of employers and workers. These guilds would not do away with the necessity for apprenticeship.—Another paper was read by Dr. J. Fleming, who said that the country should be covered with evening classes, and there should be a multiplication of such colleges as that at Finsbury. A discussion then ensued, among those who took part in it being Mr. H. Cunynghame and Mr. Bartley, M.P. Dr. Lant Carpenter moved, and Mr. John Ward (a working man) seconded, the following resolution:—"That this meeting desires to express its strong opinion of the urgent need, not merely of a well-considered scheme of technical education, but of such preparatory educational measures as will render that system of the greatest possible service." Dr. Carpenter said that the discussion would be resumed at a further conference, to be held early next year. The resolution was carried unanimously.

The "Sun" Portable Electric Lamp.—*The Times* of 13th December contains the following:—"A new form of portable electric lamp has just been brought under our notice, the primary object of the inventor, Mr. Urquhart, being to utilise it as a miners' lamp. It is, however, said to be equally applicable for domestic and every other class of electric lighting. As a miner's lamp it weighs 4lb. 2oz. and gives a good all round light for ten hours. It is a modified form of secondary battery, and possesses the great advantage over other batteries of that class that it can be fully charged with a ten hours' supply of current in four hours. The

Digitized by Google

cell or casing is 6in. high and 3½in. in diameter, and has a small glow lamp of 1¼ candle-power mounted on the top. The positive element is zinc, of which there are two plates, the negative element being a plate of special metallic alloy. These elements are suspended in a depolarising solution of dilute sulphuric acid mixed in the proportion of 10 to 1. The battery can be used as a primary, but is at its best as a secondary battery, charged from a dynamo in the usual way. The cost of the miners' lamp is stated to be one guinea, and the cost of maintenance 3d. for six shifts of ten hours each. There is no waste going on while the lamp is not running, although the elements remain suspended in the solution. The case is strongly bound with metal and the glow lamp is protected first by a toughened glass dome, and secondly by a cage of stout brass wire. Absolute safety against risk of explosion, should the glow lamp glass be broken, is insured by an ingenious automatic contrivance in connection with the toughened glass dome. Should this dome be fractured the circuit is broken and the light is instantly extinguished whether or not the glass of the glow lamp be broken. The lamp is being introduced by the New Portable Electric Lamp and Power Syndicate, who have had some of the lamps tried at the Dukinfield Colliery, near Manchester, with every success. This lamp, among others, was exhibited at the reading of Sir Frederick Abel's recent paper on mine accidents, and met with commendation from him. Since that time, in order to test it for safety in a thoroughly practical way, some lamps were placed in the hands of Mr. C. E. Rhodes, the manager of Aldwarke Colliery, Rotherham, who states that he is much pleased with them, the light given being equal to four of the best oil lamps."

Prof. Ewing's Lectures on Electric Lighting.—On Monday evening last Prof. Ewing, at Dundee, brought his course of popular lectures on Electric Lighting to a close, the subject of the final lecture being the cost of electric lighting for factories and domestic purposes. Taking the case of a factory, where the necessary engine power was already provided, he said that the first cost of the whole electric plant, including dynamo, wiring, lamps, and fittings, was a little less than £2 per lamp, provided the number of lamps was over 200. He then considered in detail the cost of lighting a factory with 400 lamps. The first cost of the electric plant was £800, which represented an annual charge of, say, £88 on account of interest and depreciation. The current outlay for coal, oil, and lamp renewals was considered in detail, and shown to be about 2s. for each hour that the lamps were in use. If the lamps were only used for a small number of hours in the year the whole working cost was high, because the charge for interest and depreciation had to be spread over that small number of hours; but if the number of hours in use was large electricity was found to be much cheaper than gas. There was a particular number of hours of annual lighting which made the cost of electricity just equal to that of gas. This number was 425 hours. Hence, if a mill worked only by day there was little or no direct economy (though there were other advantages) in the use of electric lamps as compared with an equal number of gas burners; but if night work was done there was a very distinct economy. Thus, if the 400 lamps were needed for 3,000 hours in the year, the whole annual cost of lighting by electricity would be £388, as against £918 for gas. The lecturer went on to speak of the cost of domestic lighting, and pointed out that it was very great where each householder had to supply his own electricity. By co-operation, however, it might be reduced to a more moderate figure, though it remained, and apparently would remain, for some time dearer than gas. The inhabitants of a square or terrace might combine, each agreeing to take a certain number of lamps at an annual rental. Taking an imaginary case, where 500 lamps were supplied in this way, all within a reasonable radius, and with sufficient storage capacity to supply night lamps when they might happen to be wanted, the lecturer found that the capital cost would be £2,200, and the annual charge, including interest and depreciation, would be £625. Thus the co-operative scheme would pay the expenses if people appreciated the advantage of electric lighting enough to pay 25s. per lamp as the annual rent. Particulars were given of the public installations in London, Brighton, Antwerp, Berlin, Hanover, Milan, Tours, and Vienna, where in the aggregate many thousands of lamps were in use. At these places the public were supplied with the electric light at a charge which was usually a little less than ½d. per lamp per hour.

The Formulæ of "Dimensions" in Electricity.—M. Lippmann, in a note in the *Comptes Rendus*, points out that the formulæ of "dimensions" in electricity affords a criterion of the maximum theoretical simplicity of any experimental method of measurement. In other words, the formula indicates the character of the measurement (of length, mass, or time) to be made, which is the necessary and sufficient condition for obtaining the numerical value of the quantity sought in absolute units. One or two examples will make this clear. (1) In absolute electrostatic units capacity has the dimensions of length. The principle which has been laid down leads, therefore, to the conclusion that there must be some, at least conceivable, method by which the capacity of a conductor could be determined in absolute units without the necessity for making any other than a single linear measurement; and this measurement must be numerically equal to the capacity sought. The following is M. Lippmann's solution. Suppose that we are required to determine the capacity of a Leyden jar. Imagine that we are provided with a metallic sphere whose radius can be varied continuously. We can then easily adjust the size of the sphere until its capacity is equal to that of the jar, and this can be done experimentally without requiring any operation of the nature of measurement. When, however, the adjustment has been effected, we know also that the capacity of the jar and the sphere, being equal, is measured in absolute units by the radius of the sphere. (2) Take the case of resistance, which has the same dimensions as velocity. M. Lippmann shows that it is possible to conceive a method of measuring resistance depending solely on the measurement of a velocity. Returning to the familiar though imaginary experiment in which a rectilinear conductor of unit length is supposed to move through a magnetic field of unit intensity in a direction at right angles both to itself and to the direction of the lines of force; we then say that if the slider form part of a circuit of unit resistance containing no other resistance than itself, unit current will flow through that circuit when the velocity of motion is equal to one centimetre per second. M. Lippmann now bowls over all these restrictions, and allows the experiment to take place with any length of slider, any resistance, and any magnetic field. He fixes attention, however, upon a point, P, situated at a constant distance from and in the rear of the slider, and in its plane, *this distance being equal to twice the length of the slider.* [It would seem that M. Lippmann exceeds here the limits which he assigns himself.] Now if a magnetic pole be placed at the point P, there will be a certain velocity of motion at which the magnetic field due to the current in the slider will at the point P exactly counterbalance the effect of the generating field, and consequently a small needle at this point would undergo no deflection. It can now easily be shown that the velocity of the slider is numerically equal to its resistance.

I.—BRIGHTON.

(Continued from page 102.)

The Brighton Ammeter.

Mr. Wright has in use a very simple form of ammeter, in which the principle made use of is that of the repulsion of similar poles. It is obviously more easy to get a proportionate scale in an instrument based upon the principle of repulsion than upon that of attraction. In the former case, with small currents, the armature occupies the position where the rate of change of strength of field is greatest and the instrument is most sensitive; while the reverse is of course the case with instruments depending on attraction. This fact is so obvious that it can only be a matter for surprise that so little advantage has hitherto been taken of it by instrument makers. In the earlier (1884) type (Fig. 4) of this instrument a pair of solenoids are mounted one above the other, with their coils so connected that the cores are of similar polarity at either end.

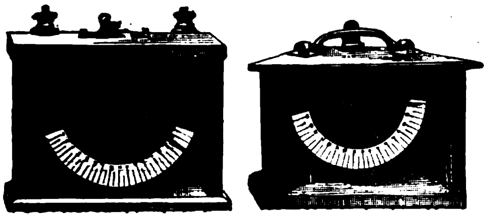

Fig. 5. Fig. 4.

The lower core is fixed, and is provided with a pole-piece bent upwards at right angles and then cut off obliquely as shown. The upper core is of the same shape, but is pivoted at either end, so that the horizontal portion is free to rotate on its own axis; the vertical portion carries an index needle and a counterbalance. The weight of the counterpoise and the shape of the pole-pieces are carefully adjusted, so that the deflections are nearly proportionate throughout the entire length of the scale, which extends over 140 degrees.

The next step obviously consists in placing both cores side by side within a single solenoid; this pattern (first made in 1885) is shown in Fig. 5. The chief, perhaps the only, defect in these instruments as continuous current ammeters lies in the variation of the reading between ascending and descending currents of the same value. This can, however, be obviated by making it a rule to short-circuit the instrument between any two readings.

The E.M.F. Recorders.

In Fig. 6 is seen the automatic apparatus by which the fluctuations of the E.M.F. are automatically registered from instant to instant. There are usually four recorders at work registering on separate circuits, and it is extremely interesting to watch their movements. The apparatus consists of a solenoid in series with a resistance of 80,000 ohms, and connected as a shunt to the mains. The solenoid is provided with a core which is attached to the bow-shaped spring seen on the right hand side. A light needle extends nearly at right angles to the top of the core, and presses obliquely against a sheet of carbon-coated paper, on which it leaves a trace. The paper is moved forward horizontally by the train of wheelwork seen on the left, which is really nothing more than the interior of a cheap American clock. A weight attached to a cord passing over a pulley keeps the paper taut at the other end. The needle moves up and down vertically with every variation of the E.M.F. A similar arrangement is employed to register the variations of the current, which should, of course, trace a perfectly straight line. The trace thus taken is examined every morning, and thus a record of the rate of expenditure of energy in the circuit at any moment may be obtained. Fig. 7 is a facsimile on a reduced scale of a trace taken from the E.M.F. recorders on four circuits (north, east, west, and north-east) on April 23rd, 1887. In the actual apparatus a variation of 100 volts moves the scriber 1 centimetre vertically, while the clockwork carries the paper horizontally at the rate of 2 centimetres per hour. The N circuit includes the railway station, where a large number of arc lamps are hung; this accounts for the greater irregularity of this trace, as all the movements of the feed leave their record.

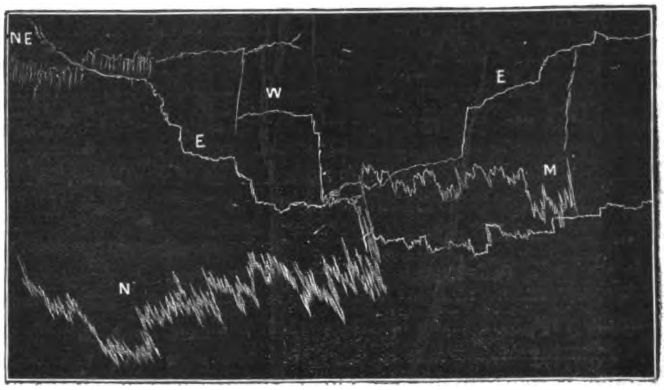

Fig. 7.

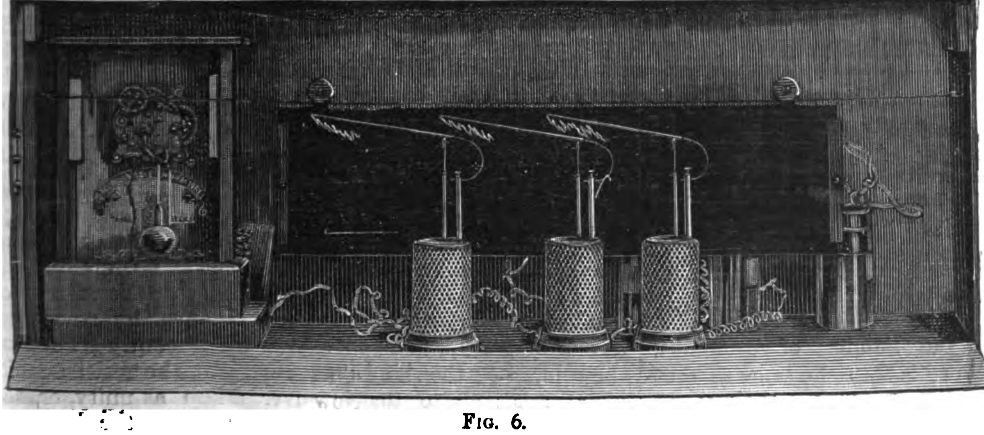

Fig. 6.

The Protectors.

In running incandescent lamps upon a constant current circuit, the "protector" necessarily forms a very important feature of the system. The object of this device is to ensure the safety of the remaining lamps upon a parallel in the event of any one lamp giving way. It is hardly necessary to remark that even when a lamp is placed *hors de combat* the full current must still traverse the parallel; the potential at the terminals of the remaining lamps therefore rises, so that if a second lamp should give way it is probable that the whole parallel would follow suit, and thus lead to a break down of the entire circuit. It should be mentioned that the "parallels" at Brighton consist either of (1) ten lamps taking 1 ampere each; (2) three lamps taking 3·5 amperes each; or (3) of one lamp taking the entire current and giving a light of 60 candle-power.

First Pattern.—The protector employed at Brighton in 1883 consisted of a series of electro-magnets equal in number to the lamps on the parallel placed in a row with their coils connected each with the terminals of a lamp. If any lamp broke, the cessation of current in the coils of its magnet released an armature which brought a spare lamp into circuit. Only one spare lamp was necessary, one of its terminals being connected to one side of the main circuit, and the other to a bar upon which any

Digitized by Google

one of the armatures could make contact. This device fully answered its purpose, but it was obviously necessary to find something cheaper and equally efficient.

Second Pattern.—This was termed the Safety-holder, in which the cessation of current in a particular lamp caused the armature of an electro-magnet contained in this lamp-holder to make contact to a third wire leading to the safety lamp of the whole parallel. This reduced the number of wires it was necessary to run to 3, instead of 11, in a 10-light parallel.

Third Pattern.—In 1884 a far more economical arrangement was introduced, and is still in use. A single electro-magnet was connected as a high-resistance shunt to the parallel. Its armature was delicately adjusted, and on the increase of E.M.F. it closed a contact, and threw into the circuit a lamp of only half the normal resistance of the ordinary lamps. The armature, after falling, was held down by a mechanical or electrical catch. This is shown in Fig. 8. The switch is mounted on the same base.

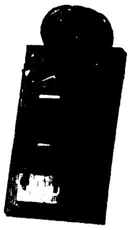

FIG. 8.

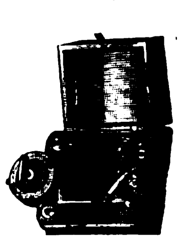

FIG. 9.

Fourth Pattern.—An additional refinement was introduced in 1885 by which, if a second lamp give out, the whole parallel is short-circuited. This is effected by causing the first contact which throws in the safety lamp to take place on a spring. If the E.M.F. again increase the armature closes more tightly, and brings the spring into contact with a terminal connected with the opposite side of the parallel, thus short-circuiting the whole set of lamps. This remedy is, of course, a somewhat drastic one, but it very seldom comes into operation, and in any case it is better to interrupt a single parallel than to break down the whole circuit. This form is shown in Fig. 9.

THE METER.

The consumers are charged by meter at the rate of 1s. per unit. Mr. Wright terms his apparatus the "Faraday" meter, as being based upon Faraday's discovery of the proportionality

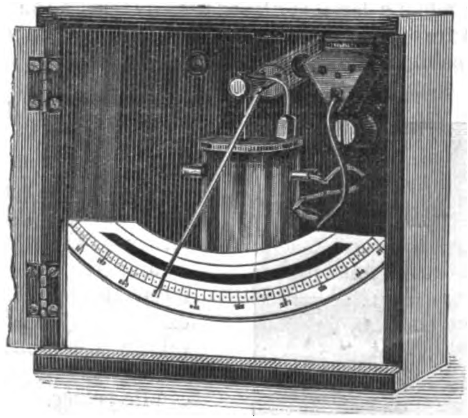

FIG. 10.

of electrolytic deposition with the number of coulombs. But although the principle employed is thus the same as that adopted by Edison in his well-known meter, yet the method of application is entirely different, and is capable of yielding far more accurate results. Edison calculates the total consumption of current by passing a known (or supposed known) fraction of the total current through the meter, and the energy supplied is calculated on the assumption that the difference of potential is constant throughout the circuit. This assumption is, of course, only approximately correct. These objections to the electrolytic method are absent when it is employed in connection with a constant current distribution. In the first place we have now to measure the "volt-hours" across the terminals of the house connections, so that the meter is a shunt to the whole installation. By placing a high resistance in circuit with the meter in order to reduce the current in the shunt circuit, no error is introduced. Secondly, by integrating the E.M.F. and assuming constant current we are introducing no non-existent factor; in fact, as we have already seen, the current at Brighton is actually maintained constant within 1 per cent.

The meter employed is shown in Fig. 10. It consists of a small glass jar containing sulphate of copper solution, with a pair of copper electrodes. This is placed in series with a resistance of several hundred ohms, made up of bare G. S. wire strung on a small wooden frame. The cathode is attached to a rod, which is bent over and pivoted at the top, and carries a weight at its extremity. The arrangement is such that as copper is deposited on from the plate the counter-balancing weight gradually rises and the pointer traverses the scale, the arm being so hung that it is in stable equilibrium in all positions. In practice it is found that the employment of an index hand which can be read as easily as a gasmeter is much appreciated by the consumers.

(To be continued.)

CHAPTER IV.

Resistance.

29. We have already seen (*see* para 14) that the resistance of any electric path is the obstruction which a current traversing it encounters, and we are now in a position to examine the nature of this obstruction more closely.

30. Of all known substances metals offer the lowest resistances, and the more common of these may again be comparatively classed in the following list, which commences with the least resisting and ends with the most resisting metal:—

Relative Specific Conductivity.		Relative Specific Resistance.
1·000	Silver (hard drawn)	1·000
0 996	Copper „ „	1·005
0·780	Gold „ „	1·283
0 290	Zinc (pressed)	3·446
0·168	Iron (annealed)	5·949
0·131	Nickel „	7·628
0·124	Tin (pressed)	8·091
0·083	Lead „	12·131
0·046	Antimony „	21·645
0·016	Mercury (liquid)	62·500
0·0125	Bismuth (pressed)	80·000

Since in this list, taken from Clark and Sabine's tables silver is the metal offering least resistance to a traversing current, it must also be the metal which most facilitates its passage—that is to say, which conducts it best. Silver is therefore said to be the metal of greatest *conductivity*. The table therefore gives the metals in diminishing order of resistance by ascent, and in diminishing order of conductivity by descent. The figures in the column on the right hand represent the resistance of each metal relatively to that of silver taken as unity, or, as it is called, the *relative specific resistance*; while the figures in the left hand column give the conductivity of each metal relatively also to that of silver as standard, or, as it is termed, the *relative specific conductivity*. Thus iron is shown to have a resistance of nearly six times that of silver, so that if a conductor made of pure hard-drawn silver were of such dimensions as to offer

Digitized by Google

resistance of one ohm, a conductor of annealed iron of exactly the same dimensions would offer about six ohms. Consequently, since iron resists a current six times as much as silver, the conductivity of silver must be six times that of iron; therefore, calling the conductivity of silver 1, that of iron must be six times less, or one divided by six—that is, $\frac{1}{6}$, or 0·167, the more exact number being by the table 0·168 $=\frac{1}{5·949}$. Similarly, the relative specific resistance of mercury being 62·5, its relatively specific conductivity is $\frac{1}{62·5}$, or 0·016—that is to say, 1·6 per cent. of pure silver; so that in all cases the specific conductivity of any material relatively to a standard material is the quotient found by dividing into unity the specific resistance of the substance relatively to the same material; and, further, the conductivity of any path is found from the resistance of that path in the same manner and is expressed in terms of a unit, to which the name of *mho* has been given by Sir William Thomson, the term conveying the inverse idea of resistance by being an inversion of the word ohm. Thus, if a certain conductor had a resistance of 0·2, 1, 50, or 7,000 ohms, its conductivity would be $\frac{1}{0·2}$, $\frac{1}{1}$, $\frac{1}{50}$, or $\frac{1}{7,000}$ mhos respectively, that is, 5, 1, 0·02, or 0·000143 mhos.

31. The relative specific conductivity of metals is always reduced by impurity, and even a very slight degree of impurity will suffice to palpably lower the conductivity, or, in other words, add to the conductor's resistance. It is by no means impossible to find a sample of impure commercial copper which will only possess the specific conductivity of zinc, owing to the admixture of foreign and non-conducting material, or of baser and more resisting metal. Also a conductor composed of an alloy of different pure metals in known proportions has generally a greater specific resistance than would be furnished by an estimate made on the supposition of its being a bundle of separate and purely metallic conductors of proportional dimensions.

32. The table also shows that pure copper is so close to pure silver in conductivity as to scarcely make it desirable to select the latter and rarer metal for conductors, even were the matter of cost entirely set aside. In telegraphy, therefore, copper is the metal employed as the conductor for submarine and subterranean purposes, while both iron and copper are used for overhead wires.

33. The resistance of a conductor of homogeneous materiel depends only upon its dimensions and temperature. So that if the temperature of a fixed conductor be constant, its resistance will be the same to every strength of current.

34. As regards dimensions, the resistance of a conductor of homogeneous material depends upon its cross-section and length. If its cross-section be constant, the resistance will be proportional to the length. Thus, if a mile of a certain wire had a resistance of 10 ohms, then the resistance of 0·02, 0·4, 7, or 5,000 miles of the same material and cross-section would be 0·2, 4, 70, or 50,000 ohms respectively.

35. With conductors of the same length and material, the resistance increases as the cross-section is reduced, just as the resistance to the flow of water through a pipe is increased as the pipe is reduced in cross-section. Thus, if two wires, A and B, are of the same length and material, but B has twice the cross-sectional area of A, then B may be regarded as being made up of two wires very close together each of A's cross-section, and therefore equal to A in every respect. Obviously the double wire would convey under the same E.M.F. double the current that would traverse the single wire A, and its conductivity, being double its resistance, would be only half that of A. Similarly, another wire, C, of the same length and material, but of three times A's sectional area, would offer one-third of A's resistance; and in the same way if C had 0·25, 0·7, 3, or 15 times the cross sectional area of A, it would offer $\frac{1}{0·25}$, $\frac{1}{0·7}$, $\frac{1}{3}$, or $\frac{1}{15}$; that is 4, 1·43, 0·33, or 0·061 times A's resistance respectively.

36. Further, since in doubling the sectional area of a given length of homogeneous wire we double the quantity of metal in it, we necessarily double the weight of the wire, so in every case the conductivity of a wire of fixed length and material will be proportional to its weight. Thus, if a wire, A, one mile long, weighing 100lb., offers 10 ohms resistance, then another wire, B, of the same material, one mile long, and weighing 200lb., would have double the cross sectional area, double the conductivity, and consequently half the resistance of A, namely, 5 ohms; and in the same way if B were to weigh 0·5lb., 2lb., or 500lb., it would offer $\frac{100}{0·5}$, $\frac{100}{2}$, or $\frac{100}{500}$ times, that is 200, 50, or 0·2 times the resistance of A respectively.

37. The conductors employed in telegraphy are wires, that is to say, are cylindrical in form, so that their dimensions are generally (1) length (on land in statute miles of 1,760 yards, at sea in nautical miles of 2,029 yards), and (2) either the diameter or the weight per mile. If the diameter is given, the sectional area is found by multiplying the square of the diameter by 0·7854. For example, a wire 0·03in. in diameter would have a sectional area of 0·03 × 0·03 × 0·7854, or 0·00071 square inch. The sectional area and weight of a wire are directly connected, for in the case of iron wire the sectional area in square inches multiplied by 17,500 gives approximately the weight in pounds per statute mile. For copper wire the similar multiplier is 20,000, but for cable core whose conductor is usually a strand of seven copper wires, the approximate weight of conductor per nautical mile is found by multiplying the sectional area found from the diameter as above by 18,100. For example, a copper strand of cable core has a diameter of 0·13in. Its area will therefore be approximately 0·13 × 0·13 × 0·7854 or 0·01327 square inch, and 0·01327 multiplied by 18,100 gives 240·2, the approximate weight in pounds of one nautical mile of this strand.

38. The problems which practically arise for solution in the case of telegraphic conductors are generally of the following form:—Having given the metal of which a wire is made, and any two of the three following particulars—dimensions, resistance, and conductivity relatively to pure metal, it is required to find the third. Leaving the effect of temperature at present out of consideration—that is to say, supposing that the temperature remains constant—we shall find no difficulty in solving any such problem, as the following cases will show:—

(*a*) Having given the dimensions and resistance, to find the conductivity.

Example.—A copper strand conductor of cable core 5 knots long and 0·096in. in diameter gives a resistance at the standard temperature of 48·42 ohms. What is its conductivity compared with pure copper?

The sectional area of the strand is 0·096 × 0·096 × 0·7854, or 0·007238 square inch approximately. Its weight per knot is therefore 0·007238 × 18,100, or 131lb. As may be seen in electrical tables, the resistance of a wire of pure copper one knot (nautical mile) long, and weighing altogether 1lb., would be 1196·7 ohms at the standard temperature of 75° F.; consequently, the resistance of a wire of pure copper one knot long and weighing 131lb. would be (36) at the standard temperature $\frac{1196·7}{131}$, or 9·135 ohms, and hence its conductivity would be $\frac{1}{9·135}$ mho, that is 0·10947 mho. The wire in question offering 48·42 ohms is five knots long, so that one knot would offer $\frac{48·42}{5}$, or 9·684 ohms, and the conductivity of one knot would therefore be $\frac{1}{9·684}$, or 0·10326 mho. The conductivity of pure copper is to the conductivity of this wire, therefore, in the proportion of 0·10947 mho to 0·10326 mho

Digitized by Google

—that is, as 1 is to 0·9433, or as 100 : 94·33; so that the wire's conductivity is thus $94\frac{1}{3}$ per cent. that of pure copper.

(*b*) Having given the dimensions and conductivity, to find the resistance.

Example.—A copper wire 600 yards long and 0·25in. in diameter has a conductivity 96 per cent. that of pure copper. What will be its resistance at the standard temperature?

The sectional area is in this case of a cylindrical wire, not a strand, strictly 0·25 × 0·25 × 0·7854, or 0·0490 square inch, so that its weight per statute mile will be 0·049 × 20,000, or 980lb. approximately. The resistance of a statute mile of pure copper weighing one pound may be seen in electrical tables to be 872 ohms at the standard temperature, which for overhead land lines is generally taken at 60° F. A wire of pure copper weighing 980lb. per mile would therefore have a resistance of $\frac{872}{980}$, or 0·8898 ohm, and its conductivity will thus be $\frac{1}{0·8898}$, that is, 1·1238 mho; but its conductivity being only 96 per cent. of pure copper will be 96 per cent. of 1·1238, or 0·96 × 1·1238—that is, 1·0789 mho, or $\frac{1}{1·0789}$, namely, 0·9268 ohm per mile. But the wire in question is only 600 yards long, and will therefore have less than this resistance in the ratio of 600 to 1,760, so that its resistance will finally be $\frac{600 \times 0·9268}{1760}$, or 0·316 ohm.

(*c*) Having given the resistance and conductivity, to find the dimensions.

Example.—A length of homogeneous cable strand conductor, 0·133in. in diameter, is known to be of 97 per cent. conductivity compared with pure copper, and has a resistance at the standard temperature (75° F.) of 37·5 ohms. What is the length of the conductor?

The area of this wire is approximately 0·133 × 0·133 × 0·7854, or 0·013893 square inch. Its weight per knot is therefore 0·013893 × 18,100, or 251·5lb. The resistance of a wire of pure copper one knot in length and of this weight would be $\frac{1196·7}{251·5}$, or 4,759 ohms at the standard temperature. Its conductivity would therefore be $\frac{1}{4·759}$, or 0·21013 mho. The wire in question, however, having 97 per cent. of this conductivity, would have only 0·21013 × $\frac{97}{100}$, or 0·20382, and therefore a resistance of $\frac{1}{0·20382}$, or 3·988 ohms, but its total resistance being 37·5 ohms, its length must be greater than one knot in the proportion of 37·5 to 3·988, so that its length will be $\frac{37·5}{3·988}$, or 9·425 knots.

The steps in all these calculations can of course be very much abbreviated when the method is clearly understood. Thus, the example in (*b*) is capable of being worked out directly by one fraction in the following form:—

$$\frac{872 \times 100 \times 600}{0·25 \times 0·25 \times 0·7854 \times 20000 \times 96 \times 1760}$$

that is, 0·316.

(To be continued.)

THE SCHANSCHIEFF BATTERY.

We have recently had an opportunity of examining the Schanschieff battery at 65, Basinghall-street, the offices of the Schanschieff Battery Syndicate, where a small installation is at work. There is, of course, nothing especially novel in the use of a zinc carbon couple with sulphate of mercury. Marie Davy did it long ago. The sulphate solution has, however, up to now been a very weak one—somewhere about 1 in 2,000 of water. M. Schanschieff's success has resulted from his discovery of a method by which a much stronger solution is obtained. This is almost the only novelty about the cell, but it is an important one, for it gives us a single-fluid battery which has low internal resistance, tolerably high E.M.F. (1·39 volt), freedom from smell of any kind, combined with an almost perfect freedom from polarisation. The mechanical details appear to have been carefully worked out, especially in the miners' lamps, of which several patterns were shown. Sir William Thomson has reported very favourably on a cell which he has tested, and considers it "remarkably perfect, and certainly better than any other single-fluid battery yet invented."

Mr. Preece has also tested a miner's lamp, and reports equally favourably. In a very careful test he has obtained a 1 candle-power light for eight hours at the cost for materials of one penny. There is said to be no appreciable local action when the cell is in use, and the plates are withdrawn from the solution when not in use.

The solution is supplied ready made at 4s. per gallon. By the action of the cell the mercury sulphate is nearly all reduced to metallic mercury, for which, with the partially exhausted liquid, 3s. 7d. per gallon is allowed, thus making the price 5d. per gallon, without carriage, and one fluid ounce of liquid per cell gives one ampere-hour, or 160 ampere-hours for 5d. At 1·2 terminal E.M.F. this is equivalent to 192 watt-hours, which with the cost of zinc gives about 1d. per hour for a 10 candle-power lamp.

We also saw various other forms of the battery for one or two 5 candle-power lamps, and a six-cell battery fitted into the top of an ordinary London and South Western Railway carriage lamp to give a 5 candle-power light for 10 hours. There were also some large boxes which had been made for a torpedo boat, which were 19in. by 9in. by 24in. high, each containing four cells, and giving 0·2 horse-power per box for 10 hours. Altogether we were favourably impressed with the battery, and should imagine there would be a large field for it for small work, say up to three 5 candle-power lamps for domestic use and for mining purposes.

ON THE APPLICATION OF THE DECI-AMPERE OR THE CENTI-AMPERE BALANCE TO THE DETERMINATION OF THE ELECTROMOTIVE FORCES OF VOLTAIC CELLS.*

BY SIR WILLIAM THOMSON, F.R.S.

The method described in this paper for the determination, in absolute measure, of the electromotive forces of voltaic cells, consists in the use of one of my standard ampere balances instead of the tangent galvanometer in the method given in the following statement,† which I quote from Kohlrausch's "Physical Measurements," pp. 223, 224, 230:—"The only methods applicable to inconstant elements, of which the electromotive force varies with the current strength, is to bring the current to zero by opposing an equal electromotive force. Poggendorff's method, which is very convenient, as it involves no measurement of internal resistance, requires the use of a galvanoscope, G, a galvanometer, T, and a rheostat, R, and, in addition, that of an auxiliary battery, S, of constant electromotive force, greater than either of those which are to be compared. The arrangement of the experiment is shown in Fig. 1. In the left division of the circuit are the galvanoscope G, and the electromotive force E to be measured; in the right, the auxiliary battery S, and the galvanometer T. E and S are so placed that their similar poles are turned towards each

* Communicated by the author, being a Paper read at the Manchester Meeting of the British Association, with additions. [The paper in its original form appeared in our issue of September 16th.]

† Kohlrausch was, I believe, the first to show that Poggendorff's method, when a standard galvanometer is available for measurement of currents in absolute measure, can be applied to the determination of the *electromotive force of a cell in absolute measure.* Poggendorff's method, as generally given, is merely for the comparison of the electromotive forces of two cells.

Digitized by Google

other. In the middle part of the circuit, which is common to both batteries, is the rheostat R.

"As much rheostat resistance, W, must now be intercalated as will cause the current in E G to vanish, and the current strength J in T must then be observed. . . If J = current strength in T, the electromotive force of the battery E is E = WJ."

The deci-ampere balance, or, when a sufficient number of battery cells is available, the centi-ampere balance answers well for the current measurements here required. An arrange-

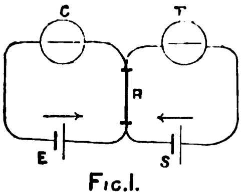

Fig. 1.

ment of the circuit which is convenient for most purposes is shown in the diagram (Fig. 2); but it may be remarked that the reversing-keys there shown may be replaced by ordinary make-break keys. Referring to the diagram, a battery of a sufficient number of cells is joined in circuit through a reversing-key with a rheostat, a deci-ampere balance, and a standard resistance. The poles of the cell to be tested are connected in circuit with a key and a sensitive mirror-galvanometer to the two ends of the standard resistance in such a way that both the battery and the cell to be tested tend to send a current in the same direction through that resistance. Care should be taken that the circuit of the cell to be tested is well insulated, and that both it and the standard resistance are free from other electromotive force. When, as in the case of Clark standard cells, the cell is incapable of maintaining a current, a high resistance galvanometer or an additional resistance should be included in its circuit. If very great sensibility is not required, a quadrant electrometer may in such cases be substituted for the galvanometer. The standard resistance must be of such a form that no sensible error is introduced

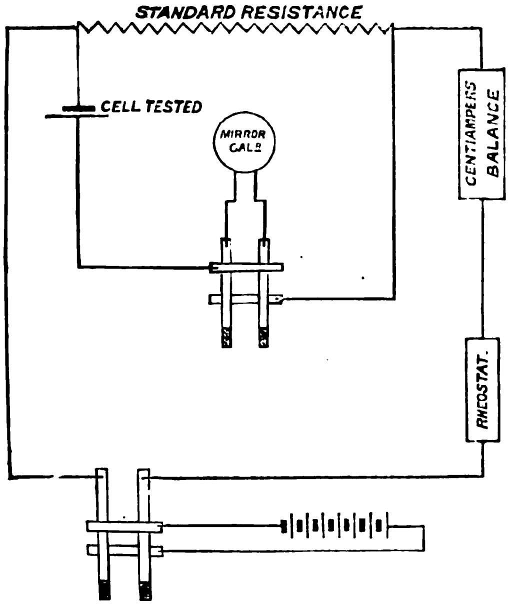

Fig. 2.

through heating by the passage of the current. A good plan is to wind well-insulated platinoid wire in one layer on the outside of a brass or copper cylindrical vessel which can be filled with water. The temperature of the water, when it is nearly the same as that of the air outside, will be very approximately the temperature of the coil. For still greater accuracy the cylinder may be fitted with a jacket and immersed in a vessel of water, and appliances introduced for changing the water in each part and keeping account of its temperature. For use with the deci-ampere balance, a platinoid resistance of two ohms is sufficient for any single cell. A resistance of two ohms, made of insulated platinoid wire one millimetre in diameter, and wound on a brass tube capable of holding half a litre of water and simply exposed to the air outside, will carry a current of one ampere for an hour without changing its resistance more than a tenth per cent. The water should be stirred when the readings are taken, and, if necessary, the change of resistance can be approximately allowed for by taking its temperature. To measure by means of the deci-ampere balance an electromotive force of from one to two volts, a battery of two small secondary cells or four Daniell cells, a resistance of two ohms such as has just been described, with the other appliances as indicated in the figure, are all that is necessary.

The method has been applied in my laboratory by Mr. Thomas Gray for the measurement of the electromotive forces of standard and other cells, and has been found very convenient. The results obtained for four Clark standard cells set up by Mr. J. T. Bottomley in March last were almost identical with one another, and gave 1·439 Rayleigh, or 1·442 legal, volts at 11deg. C. The variation of the electromotive force of these cells with temperature has not yet been determined; but assuming the average value obtained for this variation by Lord Rayleigh, namely, a fall of ·077 per cent. per degree centigrade rise of temperature, and correcting to 15deg. C., we obtain slightly under 1·436 Rayleigh volts at that temperature. This result is interesting as showing a difference of less than $\frac{1}{15}$ per cent. from that obtained by Lord Rayleigh for similar cells, which was 1·435 at 15deg. C.

MEETINGS OF SCIENTIFIC SOCIETIES.

(Week ending Thursday, 22nd December.)

TO-DAY, Friday, December 16th.

Institution of Civil Engineers.

7:30 p.m. Students' Meeting.

MONDAY, December 19th.

Inventors' Institute.

8 p.m. Ordinary Meeting. Various Papers on "Inventions Suitable for the Household." Mr. H. H. Collins, F.R.I.B.A., &c., will preside.

Society of Arts.

8 p.m. Cantor Lecture.—Series I. "The Elements of Architectural Design." By Mr. H. H. Statham. Fourth part.

TUESDAY, December 20th.

Institution of Civil Engineers.

8 p.m. Further Discussion of Dr. Edward Hopkinson's Paper on Electrical Tramways.

WEDNESDAY, December 21st.

Royal Meteorological Society.

7 p.m. Papers to be read:—

"Mean Temperature of the Air at Greenwich from September, 1811, to June, 1856." By H. S. Eaton, M.A., F.R.Met.Soc.

"Report on the Phenological Observations for 1887." By the Rev. T. A. Preston, M.A., F.R.Met.Soc.

"Earth Tremors and the Wind." By Prof. John Milne, F.R.S., F.G.S.

"Pressure and Temperature in Cyclones and Anti-cyclones." By Prof. H. Allen Hazen.

THURSDAY, December 22nd.

Society of Telegraph-Engineers and Electricians.

8 p.m. Further Discussion on Mr. A. Cockburn's Paper on "Safety Fuses for Electric Lighting."

Royal Society.

4:30 p.m. Ordinary Meeting.

*** Particulars of meetings to be held or papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

"The Electrician" in America.

"THE ELECTRICIAN" *can be obtained in America from* D. VAN NOSTRAND, *23, Murray-street, and 27, Warren-street, New York.*

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December, 1887.

All particulars relating to Advertisements will be at once forwarded, on application.

NOW READY.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

With the *conversazione* given by Sir CHARLES and Lady BRIGHT, at the Institute of Painters in Oil Colours last night, an eventful and anxious year for the SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS was brought to a brilliant and satisfactory termination. It would be idle to disguise the fact that in the autumn of 1886 widespread misgivings were felt at the prospects of the coming year, and those misgivings found a definite expression in the pages of this journal. The Society had several matters in hand of considerable importance to the scientific and commercial interests associated with its public reputation and influence. Besides this there was the Telegraph Jubilee to be celebrated in a manner worthy of the occasion and the country. Never in the career of the Society had there been a time when so much depended upon the vigour, dignity and tact of its President; and never, as it seemed to many of its leading members, had the risk of failure seemed so imminent. As we were foremost in giving expression to these apprehensions, we are now desirous of being equally prompt to acknowledge that they have been falsified by the event. The Society, if it has not gained in strength, is not seriously weakened; the attendance has been up to the average, and the papers discussed have maintained their customary excellence. As to the Jubilee banquet, its organisation and management reflected the highest credit upon everybody concerned, and it certainly took a distinguished position among the festivities of the year. In short, although the President's health, which was the chief cause of anxiety, has unfortunately prevented him from taking so prominent a part as his eminence entitled him to in these matters, the Council have supplied all deficiencies, so that the credit of the Society has sustained no injury.

In the president-elect for the ensuing year the Society will have the advantage of possessing a man who already enjoys popularity among its members, and whose sober judgment and business capacity promise well for its management. There are several questions of importance still to be settled relating to the work of the Society and its future sphere of action, all of which will tax its administration to the utmost. Among the former we may mention the proposed increase in the frequency of its meetings, an alteration which will certainly be needed if the contemplated change of its title be carried out. Of the Society's committees on the Electrical Standard Laboratory and the Fire

Digitized by Google

Office Rules, mentioned in the annual report, we expressed our opinion at the time they were proposed. In its original conception the former was open to the objection common to all proposals for subsidising science from public funds. This may not be the shape the idea has finally taken; but the committee's report will be waited with some curiosity. We have stated in a note what precisely are our views on the Fire Office Rules; and need only add here that nobody will be more gratified than ourselves if the Society succeeds in stamping with its high authority rules which shall command the adhesion of all the Insurance Offices. It is fitting and desirable that such rules should emanate from a competent and recognised body of electrical experts. The danger is that such a body may forget that it cannot impose its dicta either on the offices or the public. On the other hand, the Insurance Offices have much to gain by accepting authoritative guidance; and if they decline to do so on insufficient grounds they will incur a grave responsibility.

With regard to the proposed alteration in the title of the Society, a matter of such serious import cannot be fully discussed in the present article. There is no mistaking, however, the meaning of the change; and we suppose we must take some of the credit—or the blame, whichever suits our critics best—for bringing it about. Before the Society changed its title, or rather enlarged it, once before, we had strongly advised the adoption of a single comprehensive designation which would cover the ground then vacant. Since that time the field of electrical science and industry has widened considerably, and no choice could be better than the one to be submitted for the approval of the Society's members early next year. That this journal has had something to do with the particular title recommended will be pretty generally understood; and to some people it may look like taking the wind out of our sails. It would be nearer the truth to say that we have supplied the wind at whose bidding the sails of the Society have been set. But that is a small matter. It will rest with the members of the electrical engineering profession on the one hand to decide whether the Society under a new title, and with wider aims, is likely to satisfy their wants; and on the other, whether the society will be able to submit a programme, as well as a title, that may reasonably fulfil these requirements.

There is another body of men, however, to be consulted, namely, the Telegraph-Engineers, and to these the proposed change in the title of a Society hitherto peculiarly identified with their profession may not be wholly agreeable. But seeing that the Society gained strength when it included electricians other than those connected with the telegraph, the probability is that it would be still further re-enforced by embracing all the electrical professions. "The Institution of Electrical Engineers" would almost certainly do this, and with gratifying results to the Society and everybody belonging to it. Latterly a large number of young electrical students have been attracted to The Society of Telegraph-Engineers and Electricians for lack of a better. On these young men the Society will largely depend in the future for recruiting its members, and the surest way of attaching them permanently to it will be to reconstruct the Society on a basis more conformable to the profession to which the majority of the students will eventually devote themselves.

It will be seen from this that we heartily approve of the projected Institution of Electrical Engineers, and that in advocating as we have done a trade association of that name there is no desire to see the old society play the part of Mr. Macquoid's discarded grey mare, whose pathetic gaze after her master's new mount attracted such notice on the walls of the West Gallery last night. We have not suggested any "New Love" in the place of the old, but merely the addition of a serviceable nag on which a man of business may ride to market. As we have already observed, it remains with electrical engineers who strongly desire a business association complementary to the existing societies whether they will, in the changed circumstances, push forward their own scheme. Much may depend upon what the Society of Telegraph-Engineers intend to do, and how soon they do it; but in the long run, it seems to us, a business or trade association with a wider scope than the one now being advanced will be necessary, and will be the more easily constructed on the Society's new and broader foundations. The Association scheme has taken a narrower basis than, for our own part, we have thought desirable. Something may now be learnt from the action of the parent Society. When the time comes for seriously discussing these several questions we shall lend our voice, as heretofore, for upholding every useful institution; but we shall not be deterred from advocating the formation of new ones by the jealousy of our enemies or the timidity of our friends. There was another picture that attracted some attention at the *conversazione* last evening. It was Mr. Wardle's little dog frightened by a flock of hissing geese. The geese have quite a brave air; but then the dog is only a very young puppy.

THE PATTEN DOUBLE-ROTATION DYNAMO.

The fact that the output of a dynamo machine for a given weight of material increases rapidly with the speed at which the armature is driven has frequently led to the suggestion that the field should be rotated at the same time in the opposite direction to the armature, but the mechanical difficulties of this construction have hitherto stood in the way of its satisfactory realisation. Lieut. F. J. Patten (of the U.S. Army) has recently designed a machine of this description, of which the following description is given by the New York *Electrical World*:—

A firm and rigid structure having but a single spindle or axis and only two bearings, the least that any machine can have, and giving a continuous unbroken circuit through both armature and field while in motion, are the essential conditions to be met in order that such a system of construction shall give the double output clearly indicated by the theory of the problem.

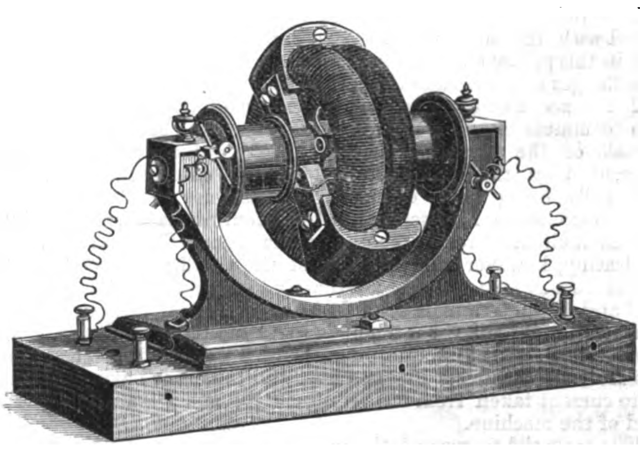

Fig. 1.

The engraving, Fig. 1, shows a perspective view of one form of generator constructed upon this system, and Fig. 2 represents a vertical section through the axis of the machine, from which the arrangements of the parts will be readily understood. F F is a rigid frame or support of cast-iron resting upon a base plate, B B.

Driven through and secured immovably in the upper extremities of the frame is a heavy steel spindle, X X, which constitutes the single axis of the machine and upon which are suspended the revolving parts, both of which turn freely upon the same fixed spindle. Q Q is a heavy pulley provided with internal boxes, to the inner end of

which is secured an arbor, M M. This arbor carries the circular field-magnets F M, having projecting field poles, N and S. An exactly similar pulley, P P, at the opposite extremity of the spindle is provided with a similar arbor, A A, which carries the armature of the machine. Thus the two revolving parts are suspended freely upon a single spindle or axis, which is held rigidly in the supporting frame.

Evidently the brushes in any machine designed for the generation of direct currents must maintain a fixed relation to the poles of the field or the neutral line. To secure this with a revolving field, a movable collar, *c c*, is carried upon the inner extremity of the pulley Q Q, to which the field is secured, and this collar is provided with arms that carry the brushes *b* and *b*, which, turning with the field, maintain constantly their proper relation thereto. In a similar manner the commutator C C is fixed upon a projecting cylinder that forms the inner end of the pulley to which the armature is secured. Arranged thus, the position of the brushes upon the commutator is evidently independent of the relative speed of the two parts of the machine, and the brushes remain at the non-sparking point whether the speeds of the armature and field are alike or different. For continuous currents a single circuit traverses the entire machine while in motion precisely the same as were the field at rest.

The current generated in the armature is taken from the brushes in the usual way, and either direct or as a shunt traverses the coils of the field. The terminals of the coils are then led through the two passages in the pulley Q Q, and are attached to the two insulated rings secured to the outer face of this pulley concentrically and insulated therefrom. These rings constitute the terminals of the internal circuit from which the brush contacts T + and T –, supported upon the frame F, transmit the continuous current to the external circuit.

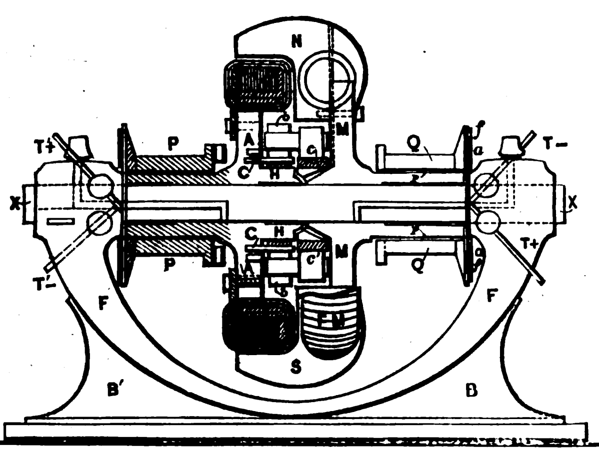

Fig. 2.

The pulley P P, which carries the armature, is similarly provided with insulated rings, *f′ a′*, secured to its outer face. There are in this pulley similar connecting channels through which these two flanges may be made the terminals of the armature coils direct, either in series or otherwise, and the brushes being removed from the commutator, the terminals T′ + and T′ – become the terminals of the armature circuit, through which an alternating current may then be delivered to the external circuit. All the coils being thus connected it becomes evidently necessary to excite the field separately by a continuous current led into the field circuit through the opposite terminals T + and T –. As indicating, however, the flexibility of the machine the coils of the armature may be connected alternately to the commutator segments C C and to the terminals on P P in pairs successively around the armature. Where the machine is so connected it will supply current to two distinct circuits, one having a continuous current and fed from the terminals T + and T –, and the other having an alternate current taken from the terminals T′ + and T′ – at the opposite end of the machine.

The essential feature of the machine or system of construction lies, however, in its evident possibility of developing a high armature velocity with a comparatively low speed. This statement, though apparently paradoxical, is nevertheless true, for both parts may be driven at a speed far within the usual limits of practice, say 300 or 400 revolutions per minute; and the resultant speed of armature through field with this rate of motion, which determines the output of the machine, or its capacity for transforming mechanical into electrical energy, will correspond under the given conditions to an armature speed of 600 or 800 revolutions per minute, as the case may be. The system is, however, capable of the highest possible speeds attainable, as will be evident from an inspection of the mechanical arrangement of the different parts.

The frame F holds the spindle X X rigidly fixed, and both parts in revolving might tend to set up vibrations in the machine and tend to shake the structure; but, owing to the opposite revolution of the parts, the action produced by one revolving part is counteracted and neutralised wholly or in part by that of the other, and as the resultant action is that due only to the preponderance of the effect of one over that of the other, they produce but little resultant effect, and the machine can be driven at a high speed without perceptible jar to the machine or the surrounding structure.

To effect the double revolution of the two parts in opposite directions it is only necessary to twist one of the driving belts from the countershaft; but, if preferred, it is a simple matter to drive both the pulleys in opposite directions with a single belt and a single countershaft.

To accomplish this an overhead shaft is placed at right angles to the spindle X X of the machine, and is provided with a fixed and a loose pulley, the diameter of the countershaft pulleys being equal to the horizontal distance from the middle of one pulley of the machine to the middle of the other. A single belt passed over the countershaft pulley and under each pulley of the machine will then drive the latter in opposite directions with a quarter turn only on each side.

The system is applicable to any armature and to any field-magnet the form of which is susceptible of revolution upon a central axis, and the brushes and commutators may be arranged outside as well as inside. The machine and adjusting parts operated by means of a shunt circuit may be secured to the arbor and arranged to control the position of the brushes so as to maintain their contacts at the proper diameter of commutation while the machine is in motion. Evidently, for all forms of alternate current machines (the multiple fields of which are usually arranged in a circular form and are well adapted to revolution) the commutator is absent, and hence are removed all difficulties from the problem, and the highest desirable number of alternations of current are obtainable either with fewer fields than before or at half speed with the same number of fields as before.

Viewed as a system of construction for either continuous or alternating current generators, the machine is designed as one of double capacity for a given weight of wire and iron; and, according to the inventor, a given installation to transform into electrical energy a stated amount of horse-power would, with the system described, require only one-half the plant in wire and iron employed at present.

The life of the plant, Lieut. Patten holds, would be equally increased, resulting from the fact that the actual speeds may be so low, and react against each other in such a way as to make a noticeable difference in the account for depreciation.

REVIEWS.

The World's Workers: Thomas A. Edison and Samuel F. B. Morse. By Van Buren Denslow, LL.D., and Jane Marsh Parker. (London: Cassell and Co.)

If a good deal of undeserved prejudice exists in this country against American notabilities the blame may be fairly laid to the biographies supplied to us from their native land, a typical specimen of which has been reproduced by Messrs. Cassell for English readers. Except that a great part of the Edison memoir is taken up with extracts from a very indifferent book on electrical science lately published by the same firm, we should be at a loss to conjecture what claims such a book has to the attention of any sane person, publisher or reader. For turgid gush and pretentious twaddle we have hardly seen any biographical sketch to equal this. If the stories here told of Edison were true, and the words quoted as his were authentic, we could only say that his detractors have never intentionally belittled him as his biographers unconsciously have done. But we do not believe half the stories, and very little of the alleged Edisonian science. There is one, and only one, good thing in the book, and English readers will detect its significance. Edison's sister is in the habit of relating, for the delectation of Edison's worshippers, that her brother, at the age of six, on being told that some newly-hatched chicks were due to the warmth of a sitting hen, suddenly disappeared. "Would you believe it if I told you he was found in the stable coiled up on a batch of turkey eggs trying to hatch them?" No, Miss Edison, we would not, and we know that you do not expect us to. Edison's biographers dimly see that this Miss Edison is a smart sort of girl. And so do we—not at all dimly; so smart, indeed, that we refuse to credit any brother of hers with being the fantastic

Digitized by Google

and foolish person this book would make him out to be. The Morse memoir is in a little better style, but possesses no feature of novelty or interest to justify its appearance in this form.

Fortschritte der Elektrotechnik. By Dr. M. Kiliani, Dr. E. Pirani, and Dr. Karl Strecker. (Berlin: Julius Springer, 3, Monbijouplatz.)

Current electrical literature is already so large that Dr. Strecker's volume of abstracts, of which the first double part has just reached us, should prove of great value both to the student and the practical man. Its aim is to be a catalogue *raisonné* of all electrical matter which has appeared during the first half of 1887 in the principal technical journals and patent lists of the world.

The arrangement of the subject matter is extremely good and convenient for rapid reference. The whole book is divided into 19 sections, *e. g.*, "Dynamos," "Arc Lamps," "Transmission of Power," "Telephones," "Electro-Chemistry," &c. Any three or four references to each will give some idea both of the labour it has cost the authors and, on the other hand, of the labour it should save the users by enabling them to find in a moment where information on any electrical subject during the first half of the year is to be had. We may mention that considerably more than half the references are to English and American journals, and that in those cases the headings are in English; the book will therefore be of considerable service, even to those of our readers who have not mastered what Mark Twain calls "The awful German language."

The Telephone Companies of the United Kingdom. By C. L. W. FitzGerald. (London: Effingham Wilson and Co.)

This pamphlet consists chiefly of a number of articles reprinted from the *Weekly Bulletin* on the progress and financial condition of the telephone companies now in operation throughout the United Kingdom. The moral of the story appears to be that the Postmaster-General ought to make haste and buy up all the plant and goodwill of his aggressive competitors. It is to be hoped that investors will not be tempted by this very problematical and remote contingency. Mr. FitzGerald's compilation, however, will be found useful for reference in regard to the affairs of the various telephone companies.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(Continued from page 52.)

Protonitrate of Iron.—A solution of this salt yielded a black deposit of iron in a state of fine division, interspersed with glistening particles of the metal palpable to the touch. A quantity of nitrate of potash was next added to the solution, when at first there was a slight disposition for the metal to go down in the reguline form, but after a few seconds' immersion the plate again blackened, and in less than a minute it became thickly coated with a gelatinous film, covered with hydrogen bubbles of about the size of mustard seed, which remained on the plate for at least half an hour, being coated with a thin rusty film. On leaving a fresh plate in the solution for about an hour, nearly the whole of the iron was thrown down in the form of a black or greenish-black gelatinous mass, which oxidised with great rapidity. A solution of the protonitrate was next made by the battery method, by passing a current from five small Daniell cells through a sheet-iron anode, suspended in a very dilute solution of nitric acid, the circuit being completed by a carbon cathode. The liquid being a good conductor, the electrolytic action was very energetic, and the iron anode became rapidly dissolved, and in less than half-an-hour metallic iron, in the form of granules, was deposited upon the carbon. A copper plate was now substituted for the carbon, which at first received a dark grey metallic film, but in the course of a few moments the deposit assumed the form of a black gelatinous mass, which subsequently oxidised, forming a bright orange-yellow powder.

Double Sulphate of Iron and Potash.—A bath was prepared from a mixed solution of the respective salts, the iron salt being in excess. With three cells of the small Daniell battery, arranged in series, a fine white and very bright deposit was obtained upon a copper plate immediately after immersion, and the deposition proceeded very uniformly for half-an-hour, when the deposit became somewhat streaky; this was remedied, however, by adding more sulphate of potash. Deposition took place very freely, and the anode was considerably dissolved in the course of an hour. This is undoubtedly a very good electrolyte for the deposition of iron, and does not appear, if faintly acid, to oxidise so freely as the ammonio sulphate solution.

Further Experiments with Persalts of Iron.—In my first paper I gave the results of some experiments with solutions of perchloride and persulphate of iron, in which I was unsuccessful in obtaining deposits of metallic iron. Having recently electrolysed some other persalts of this metal with somewhat more favourable results, I determined to renew my experiments with the perchloride and persulphate with a view to ascertain if it would be *possible*, under other conditions than those which governed my former trials, to deposit metallic iron from solutions of these salts. In treating the pernitrate as explained in the last paper I succeeded in obtaining copious deposits of metallic iron in a highly comminuted condition, thereby proving that the electro deposition of iron from a persalt (albeit not in a reguline form) is possible. Gore, in his "Art of Electro-Metallurgy," page 245, states that "solutions of persalts of iron yield no metallic deposit, but are reduced to protosalts by the passage of an electric current." That this statement is not correct I will now endeavour to prove. In the first place, a moderately strong solution of pernitrate of iron yields freely a black deposit of metallic iron, which may be collected, as I have shown, and possibly employed in pharmacy. Further, I obtained a reguline metallic coating of iron upon a strip of sheet copper from a solution of the peroxalate of iron. This latter result led me to believe that if the proper condition of the electrolyte could be obtained it was probable that solutions of all persalts of iron would yield metallic deposits. To determine this I prepared a sample of perfectly pure hydrate of the sesquioxide of iron, which was carefully washed and employed in a moist state. With this I formed saturated solutions of perchloride and persulphate respectively. I then determined to try if I could obtain a metallic film upon a copper cathode from a very weak solution of the perchloride (1 drachm of concentrated solution to 3oz. of water) with the current from five small Daniell cells in series, and was pleased to find that under these conditions a film of metallic iron began to form immediately, and in a few moments the plate was covered with a fairly bright deposit of the metal; after awhile, however, the film became blackish at the lower corners. A solution of the persulphate of iron in about the same proportions was next tried with three cells, when a bright deposit of iron at once took place at the corners and lower edges of the plate, which gradually extended upwards in the form of a horseshoe, which character it maintained until the plate was withdrawn. I have frequently noticed that some weak solutions of iron—especially *very* dilute solutions—yield deposits of this form, the metal positively refusing to coat the upper portion of the immersed surface; on the other hand, instances frequently occur, not with iron alone, but with some other metallic solutions, in which the film, while absolutely refusing to form upon the lower surface of the cathode, appeared only on the surface nearest the top of the liquid. Being thus far successful with the perchloride and persulphate solutions, I next tried a very weak solution of the pernitrate. In this trial I was less successful, but when the cathode was briskly agitated in the bath a greenish, non-adherent film was obtained, which, when dried and removed from the plate, was attracted by the magnet. It was metallic iron, therefore, but only in a semi-metallic state until dried. Having thus proved that iron *can* be deposited from solutions of its persalts when the proper conditions have been arrived at, I will now proceed to describe some further experiments which have recently engaged my attention.

Peroxalate of Iron.—A solution of this salt was prepared by dissolving freshly precipitated hydrated sesquioxide of iron in

Digitized by Google

a hot and strong solution of oxalic acid. The hydrate entered into solution very freely, forming a greenish-yellow liquid. The current from five small Daniells was used, with an iron anode and copper receiving plate as before. Shortly after immersion the cathode became coated with a metallic film of a grey colour. After a few minutes' immersion a grey non-metallic pulverulent deposit rested upon the plate, which was easily brushed off, while a similar powdery film, but of a yellow colour, appeared on the immersed portion of the anode. In a short time the liquid became turbid, and a yellowish deposit was subsequently found at the bottom of the vessel.

Sesquicitrate of Iron.—A bath was prepared from this salt by digesting freshly precipitated and moist hydrated sesquioxide of iron in a hot and nearly saturated solution of citric acid; when cold the solution was diluted with about twice its bulk of water. Five Daniells were employed, when a strip of sheet copper received a deposit of iron soon after immersion. The film, however, was neither so bright nor of so good a colour as that obtained from the protosalt.

Sesquiacetate of Iron and Acetate of Soda.—A solution of the sesquiacetate was first formed by dissolving hydrated peroxide of iron in acetic acid with the aid of moderate heat. The solution was next moderately diluted (with about two parts of water), and acetate of soda crystals then added and dissolved in the liquid. With the current from five Daniells, a metallic deposit of iron was at once obtained upon a copper plate, this electrode being allowed to remain stationary in the fluid. In about a quarter of an hour the film—which retained its metallic character—assumed a greyish colour, and became blistered all over, showing that the deposit, though reguline, was non-adherent.

Benzoate of Sesquioxide of Iron.—A solution was prepared by dissolving freshly precipitated hydrate of peroxide of iron in a hot solution of benzoic acid; this acid, being very sparingly soluble, even in hot water, yielded but a very weak solution, so it was resolved to use it while still warm. The solution was a very bad conductor, and no deposit could be obtained with five Daniells, while the cathode was stationary. When this electrode was briskly agitated in the solution a slight metallic film appeared, on the upper part of the plate only. There was a moderate evolution of gas.

Benzoate of Protoxide of Iron.—A solution was formed by dissolving recently prepared carbonate of iron in a hot solution of benzoic acid. As in the previous case the solution was a poor conductor, and yielded its metal only when the cathode—a strip of sheet copper—was briskly moved about in the bath. The same number of cells were used as in the former experiment, and the solution employed hot, but only a trifling film of iron appeared upon the upper portion of the receiving plate.

Ammonio Nitrate of Iron.—This bath was prepared by dissolving iron in cold dilute nitric acid by the action of the current, the operation being kept up until the solution was as neutral as possible, when a little ammonia was added. As is the case with most other nitrates, the solution had little disposition to yield a reguline deposit of metal. A slight metallic film appeared upon the cathode for an instant, but this quickly changed into a black deposit of pulverulent iron precisely similar in character to that obtained from the persalt. This black film, which soon became very thick upon the plate, was slimy to the touch, and consisted of metallic iron in a highly comminuted state, interspersed with bubbles of hydrogen, some of which were of considerable size, and retained their position upon the plate for many seconds—probably half a minute. The black deposit was washed off the plate into a glass containing hot water, and a fresh plate immersed in the liquid, and allowed to remain stationary for about two minutes, by which time it received a copious deposit of the same character as before, which was afterwards removed by washing, as in the previous case. Several plates were coated with the black deposit in this way, and the finely-divided metal afterwards well washed, drained upon a filter, and dried. The black powder thus obtained was then placed upon a sheet of paper, and treated with the magnet in the following way:—A piece of thin paper was laid over the poles of a small horseshoe magnet—to prevent the finely-divided metal from attaching to the magnet itself—which was then drawn across the metallic particles, but at a short distance from them, when they rapidly ascended and clung to the paper, and to each other, forming a metallic fringe of about a quarter of an inch in depth and about an inch in length. The fine metal, thus suspended, was then conveyed to a second piece of paper, and the magnet withdrawn, when, of course, the metallic particles became dislodged and fell upon the paper. The remaining atoms of metal were collected and transferred in the same way, when it was found that the first piece of paper upon which the fine metal had been placed was perfectly free from particles of any kind, showing that the black deposit obtained from the solution in question consisted solely of metallic iron. It should be mentioned that when these black deposits of iron, after being drained from surrounding water, are dried slowly, a film of oxide forms upon the surface of the particles, giving the dried material a reddish tint. This does not, however, prevent the magnet from attracting them. In this experiment the anode, which was much worn, remained exceedingly bright.

(To be continued.)

ON SOME INSTRUMENTS FOR THE MEASUREMENT OF ELECTROMOTIVE FORCE AND ELECTRICAL POWER.*

By J. A. Fleming, M.A., D.Sc., and C. H. Gimingham.

(Concluded from page 111.)

Let us examine the theory of the instrument a little more closely. Let R (Figs. 4 and 5) represent the resistance of the thick wire or current coils, and let r represent the resistance of the fine wire or volt coils, and let ρ stand for the resistance of the lamp or other circuit in which the dissipation of energy is being measured. Given the ends of these thick and thin wire coils, we may then join them up to the lamp in either of two ways, as shown.

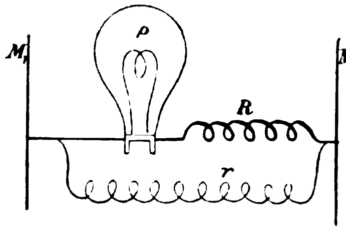

Fig. 5.

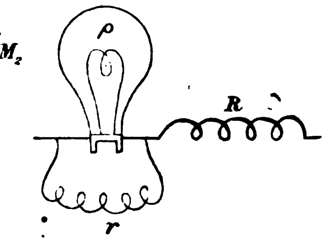

Fig. 4.

What we actually do in the use of a thick and thin wire electro-dynamometer, employed as a wattmeter, is to measure the product of the strengths of the currents in the thick and thin wire coils respectively, by measuring the electro-dynamic attraction between these circuits when held in certain fixed positions. If, however, the circuits are joined up to a lamp, although the current in R is equal to the current through the lamp, yet the current through r is not proportional to the difference of potentials on either side of the lamp, but greater by an amount which depends on the ratio of ρ to R. If W represents the true watts taken up in the lamp under measurement, and W_1 represents the observed watts by the dynamometer, on the assumption that it has been calibrated for one particular lamp of very high resistance compared with R, then

$$W_1 = W \frac{\rho + R}{\rho} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

for W_1 is made up of two factors—one a number proportional to the current in R, which is the current through the lamp, and another factor which is proportional to the difference of potentials over all between the outside terminals of lamp and resistance R.

This last is greater than the potential difference on either side of the lamp, in the ratio of $R + \rho$ to ρ.

* A paper read before the Society of Telegraph-Engineers and Electricians, November 25th, 1887.

Digitized by Google

Next let the fine wire coils be joined to the terminals of the lamp. The current in r is now proportional to the potential difference on either side of the lamp. The current in the thick wire coils is not, however, identical with that through the lamp, but equal to that through the lamp and fine wire coils together. If c stand for the current through the lamp, and C for the current in the thick wire coil R, then

$$c = \frac{r}{r+\rho} C,$$

and accordingly, if, as above, W stand for the true watts expended in the lamp, and W_2 for the watts as observed on the dynamometer, we have the relation

$$W_2 = W \frac{r+\rho}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

From equations (1) and (2) we have

$$W_1 \rho = W \rho + W R,$$
$$W_2 r = W r + W \rho ;$$

hence,
$$W^2 \frac{R}{r} = (W_2 - W)(W_1 - W) ;$$

or,
$$W^2 - \left(\frac{r}{r+R}\right)(W_2 + W_1) W + \left(\frac{r}{r+R}\right) W_1 W_2 = 0.$$

The solution of this quadratic equation gives W.

It is not difficult to show that this quadratic equation always has one real positive root, since r is greater than R, and W_1 and W_2 are positive quantities. We arrive, therefore, at this result:—If any given wattmeter of this type has been calibrated on a lamp or other circuit of which the resistance is very great compared with the thick wire or current coils, supposing the connections made as in Fig. 4, then the observed readings of the wattmeter, when used with any other lamp or circuit, will not give the true watts expended in that circuit, but give a value which is rather too high, and of which the error will depend on the value of the three resistances, R, r, and ρ. We can, however, eliminate the error, and obtain a number proportional to the true rate of expenditure of energy in the circuit ρ, by taking two observations with the high resistance coils joined up respectively, as in Figs. 4 and 5. If these readings are called W_1 and W_2, the insertion of these in the quadratic equation above will enable us to find a value (W) which is proportional to the real watts, and that without knowing the resistance of the lamp being tested.

In the construction of a wattmeter of this type it is evidently important that the current coils should have as low a resistance as it is possible to secure in comparison with that of the movable or voltmeter part. In our wattmeter the fine wire coils are of German silver wire, and have a resistance of 1,000 to 1,200 ohms. The thick wire or current coils are of the highest conductivity copper, and in the instrument designed as a lamp wattmeter, to read direct from 1 to 400 watts, have a resistance of about ·1 or ·2 ohm. It is intended to issue wattmeters of three grades—one reading from 1 to 400, the next from 10 to 4,000, and the highest from 100 to 40,000, and suitable for electromotive forces of 50 to 250 volts.

In the wattmeter above described the scale is, of course, a scale of equal divisions. In the form of instrument adapted for lamp measurements, the circular scale is divided into 400 divisions, and each division represents 1 watt. By means of a wattmeter and voltmeter of the above description all the four electric elements of a lamp can be measured at once. Let the wattmeter be joined up, as indicated in the above diagram (Fig. 4), and let, in addition, the terminals of the voltmeter be connected to the points A and B, the voltmeter then reads the potential difference of A and B, and the wattmeter reads the consumption of power between A and B. If W be the reading of the wattmeter and V that of the voltmeter, the quotient of W by V gives the current through the lamp, and the quotient of the square of V by W gives the hot resistance of the lamp. We have designed an instrument which shall be a combination of watt and voltmeter, and enable the two measurements of potential difference at extremities of a circuit and power consumed in that circuit to be simultaneously measured, and therefore to give at once the current in the circuit and the hot resistance. In this instrument the fixed coils would be wound compound, with two coils on each, one thick overlaid by a thin wire winding.

The connections of the fine wire windings on the fixed coils are so arranged in conjunction with a switch, that when the switch is turned one way the solenoids have, as ordinarily arranged, a N pole at the centre of each, but when the switch is turned the other way this pole is abolished. Hence, if a current flows through these fine wire windings in series with the movable coils, then, according as the switch is set one way or the other, the current will operate the instrument or not, and that without changing its resistance or affecting the current in the movable coils. Let, then, the thick wire coils be traversed by a main current, and the thin wire coils by a current derived by connecting their extremities to the ends of the conductor traversed by the current through the thick wire coils. The electro-magnetic force operating to displace the movable part of the instrument will be the resultant of two forces—one due to the product of the strength of the current in the thick coil and the current in the movable coil. This product is proportional to the power consumed in the conductor. Secondly, in addition, there is a force due to the action of the current in the fixed fine wire coils on the current in the movable coils in series with them. This force is proportional to the square of the current strength or to the square of the volts at the ends of the conductor. Hence, if the switch is turned so that both thick and thin wire fixed coils are operative, the electro-magnetic force on the movable coils is proportional to the watts added to the square of the terminal volts. If W be the power consumed in the conductor, and V the potential difference at its extremities, then this reading of the instrument will be proportional to $A W + B V^2$, when A and B are instrumental constants. Next, let the switch be turned so as to render the fine wire coils electro-magnetically inoperative, although not altering the resistance of the total fine wire circuit. In this case the reading of it is simply proportional to the power consumed in the conductor, or to A W. We have therefore, by two readings, the power consumed and the terminal volts of the conductor or circuit, and hence, by simple division, the current and hot resistance.

In this method of measuring a current, the movable part of the instrument is not traversed by any but a very small current, and hence the difficulty generally experienced in getting a large current in and out of a freely-moving circuit has not to be combated. In considering these instruments as permanent standards, the question obviously arises as to the permanence and perfect elasticity of the steel spring. The steel chronometer spring is made of the very best and most carefully-tempered steel. The use in chronometers justifies the statement that, when not strained beyond the limits of elasticity and when not kept in strain for a longer time than necessary to take a reading, the elasticity is perfect. There is only one caution which should be taken in using these instruments. After taking a reading, the central index hand should be turned back to zero before putting the instrument away. If the voltmeter is closed up and put on one side, with a permanent twist upon the spring, then a slight deformation of the spring may result, which will in time disappear, but not immediately. The elastic modulus which is brought into play in the use of a spiral spring is somewhat similar to that which is operative when a beam is bent. The spiral is not drawn out, but is twisted round and bent slightly into a smaller radius. Under prolonged strain a very slight deformation occurs, which disappears gradually on the removal of the stress, and this deformation is a function both of the stress or strain and the time under which the elastic body is submitted to that stress.

On this point we may quote the experience of Prof. W. Kohlrausch, who, in a paper in the *Electrotechnische Zeitschrift* (see *Electrician*, March 25, 1887), gives the result of prolonged experiments on the employment of spiral springs in measuring instruments. The effect of age, judging by observations on a brass spring extending over a period of seven years, may be completely neglected. Continuous and prolonged deformation produces a small amount of permanent set, so that the spring, when released, does not return to its original position, but this does not actually alter the indications of the instrument

Digitized by Google

if the readings are taken from the new zero thus formed. Steel is in this case less affected than German silver. Oft repeated but intermittent deformation, as exhibited by a spring of ninety convolutions and 2¼in. long being stretched so as to change from a length of 3in. to 9in. 200 times per minute for 400 minutes, introduced no sensible alteration into its subsequent indications.

An increase of temperature of 18deg F. raised the indications of a Siemens torsion galvanometer about one-tenth per cent., so that the reduction in elasticity of the spring is apparently almost equal to the decrease in moment in the magnet. Further experiments on loaded springs confirmed this conclusion, and showed that steel was again to be preferred to German silver. We think, therefore, that there is sufficient evidence to lead us to believe that the selection of a highly-tempered steel chronometer spring as a means of weighing the electro-dynamic attraction of coils traversed by currents will not be found to lead to appreciable errors.

Instruments with the suspension we have here designed and used are not very well suited for marine use, but we are engaged in arranging a mode of suspending the movable coil which will render the instruments independent of any levelling when in actual use.

TABLE OF CURRENT DENSITIFS

Current carrying capacity of the B.W.G. with densities of 1,000 to 5,000 amperes per square inch of cross section.

THE ELECTRIC CURRENT.—AN OVERLOOKED ANALOGY.*

BY PROF. F. C. VAN DYCK.

Readers of Prof. Ayrton's admirable book, "Practical Electricity," will see on page 2 a statement of that author's views as to what the electric current is *not* like.

It appears to me worth while to say something on the other side of the question, pointing out a basis of analogy between the electric current and what may be called a sound current. What follows refers to a single experimental fact, viz., that the energy developed (as heat, for instance) in an electric circuit varies as the *square* of the current in that circuit. Or, it may be put in this form, viz., the energy expended in maintaining difference of potential varies as the square of the quantity of electricity transferred from higher to lower potential.

How does this fact accord with the various hypotheses as to the nature of current? In the first place the electric current cannot be regarded as analogous to a current of *water*, for the energy of a water current varies as the cube not the square of the current. This is so important in this connection that I venture to give a brief statement of the reason for the fact by way of reminder.

To say that the energy of a water current varies as the cube of the current, because one must maintain n-squarefold head to get n-fold flow does not *explain* the matter, but really states it from another standpoint. The real explanation is to be found in the character of the flowing substance. Water is practically incompressible—that is, its volume is independent of the pressure causing flow. Hence to get n-fold current from a given orifice or tube we must force n times as many volume-units (drops) out in a given time. Therefore each volume-unit must be made to travel n times as fast as it did when unit current flowed. Consequently, each volume-unit has n-square energy, and, as there are n times as many of them traversing the orifice or tube, the energy of the n-fold current must be n-cube-fold the energy of unit current.

Now, water acts as a vehicle of energy by virtue of its *mass*. If, then, electricity is an "incompressible fluid," how does it come to pass that the energy of the electric current varies as the *square* instead of the *cube* of the current? Is there any way to explain it on the assumption that some other property than mass is efficient in the case?

In the second place, the electric current is plainly not a flow of "energy," for it cannot be that the energy of a current of energy varies as the square of the current.

In the third and last place, let us see how far an electric current is analogous to a sound current.

The idea can be given by making some suppositions and drawing inferences from them. Suppose, first, that the human ear were sensitive to sound of a given pitch only, and that sound had become a commercial quantity, transferred by conductors. A meter could easily be constructed to measure amplitude of vibration, and so "current." If the apparatus at the transmitting end of the line were worked by a spring suitably mounted, energy would have to be used to keep the spring at the requisite "potential." On these suppositions we should have—

(1) Current proportional to potential.
(2) Energy required to maintain potential proportional to the square of the current.

Just as we have in the case of electricity. It is established that static electrification is closely allied to elastic stress, and why may it not be that dynamic electricity is amplitude of vibration of some medium or media? Perhaps the difficulty of making detailed descriptions of the mechanism of the operation may be insurmountable, but it can only be profitable to insist that such a fundamental fact as the relation of current to energy must be taken into account in our theorising.

* New York *Electrician and Electrical Engineer.*

THE TAVENER COULOMB METER.

Prof. E. J. Houston, writing in the *Journal of the Franklin Institute*, describes several meters suitable for measuring alternating currents. Of the instruments discussed in this paper the Forbes meter is already familiar to our readers, and the description of the Jehl and Rupp meter is taken from our issue of September 23rd, 1887; but a meter devised by Mr. Joseph Tavener and described in an English patent (No. 123, 1884) is new to us, and possesses features of interest. The description given by Prof. Houston is as follows:—

In this meter, a double-bulbed glass tube, similar in shape to the ordinary differential thermometer, has a wire spiral in each bulb, so connected that the current to be measured can be passed alternately through the wire in each bulb.

The apparatus is poised at its centre of gravity. The current being passed through the wire in one bulb expands the air, which drives a mercury column into the other bulb. This, now, being weighted, descends, making contacts which divert the current to the other bulb. An alternate see-saw motion is thus produced, and is measured by suitable counting apparatus.

The principles involved in the operation of the Tavener meter are very clearly put forth by the inventor in his provisional specifications, as follows:—

A tube terminating in bulbs, similar in principle to a differential air thermometer, but having platinum wire or other substance, of

Digitized by Google

sufficient resistance to generate heat on the passage of a current of electricity through it, inserted through each bulb; the whole being partly filled with a fluid, such as mercury, and hermetically sealed.

This tube with bulbs, &c., rests on a support, at a point intermediate between the bulbs, and may be regarded as a hollow lever, whose support is its fulcrum, on which it turns, and whose equilibrium can be disturbed by the displacement of the contained fluid.

The whole is so metallically connected up and arranged, that on inserting it in a circuit the electric current will first traverse one bulb, heating the resistance, expanding the air, driving the fluid to the other bulb, making that heaviest, turning the lever, breaking connection with the one bulb, making connection with the other, heating the resistance contained in that, and in a similar manner again turning the lever—this action continuing so long as the current passes, but its frequency being dependent on the heat generated, which is equal to the product of the electromotive force into the quantity of current passing.

THE ELECTRIC LIGHTING OF THE CRITERION THEATRE.

The electric light has up to the present been adopted in four only of the London theatres, viz.:—The Criterion, the Savoy, the Prince of Wales's, and Terry's new theatre in the Strand.

We propose to give some account of each of these installations, commencing now with the Criterion. This theatre is lighted by about 500 incandescent lamps, and the restaurant by between 650 and 700. The lamps are supplied from 6 Edison-Hopkinson dynamos, placed in the basement below the restaurant. Five of these are used at night, the sixth being kept as a spare machine, and for use if required during the day time.

The dynamos are driven by two Armington-Sims engines of 100 indicated horse-power each, and give an E.M.F. of 105 volts at a speed of 850 revolutions.

The theatre lights are on two main circuits. The first of these includes all the stage lights, viz., 48 footlights in two main circuits, 204 lamps on six battens suspended from the ceiling of the stage, these being in six circuits, 34 proscenium lights in two circuits, and eight wing ladders carrying 80 lamps. This circuit also supplies 59 lamps on the dome of the auditorium, so that in case of one circuit breaking down the auditorium would not be left in darkness. These lamps alone if used at their full power would be sufficient to light the auditorium brilliantly.

The second circuit, which also supplies the restaurant, carries 56 lamps in the main corridor, 21 in the pit corridor, and 83 in the auditorium, arranged in three circuits.

Double-pole Edison safety fuses are placed in the switch room on each minor circuit, and wherever practicable and desirable additional fuses are placed; each of the wing ladders has its own fuse, in addition to that in the switch room.

On the occasion of our visit we were enabled through, the courtesy of the engineer in charge, to ascertain practically that the fuses were in efficient order; a small circuit containing five lamps was short-circuited as a test, and the fuse was immediately destroyed, throwing the lamps out of circuit. A single gas jet is usually kept burning in the centre of the dome, so that the jets there could be lighted at once in case of a breakdown of both circuits; but it is in a position in which it could not possibly cause danger from fire. The only other gas lights used during performances are one in a lavatory and the other on a staircase used by the company; they are both protected and so placed that it would be quite impossible for danger to arise from them.

Whenever two wires cross each other close together one of the wires is enclosed in an india rubber tube, in addition to the ordinary insulation. The connections with the wing ladders which are used for suspending on the scenery are made by covered wires, enclosed in india rubber tubes, which are passed through the stage floor and connected underneath. When the lights have to be lowered it is done in the ordinary way by the introduction of extra resistance. The whole arrangements are carried out in such a manner as to secure absolute immunity from fire as far as the lighting system is concerned. The glass of the lamps in the auditorium and corridors is ground or stippled, and is not in the least dazzling. The lamps in the dress circle and in the pit are let into the roof, and the light is thrown downwards by conical reflectors of opaque glass, producing a very agreeable light. We found the theatre wonderfully cool during the hottest part of last summer. This was no doubt due in part to the theatre being entirely below the ground level, but it certainly would not have been the case if the theatre had been lighted by gas. The electric light was first used on the 16th April, 1884, and the installation has worked satisfactorily since then without intermission.

ELECTRIC PUMPING IN COLLIERIES.*

BY FRANK BRAIN.

Before electricity is adopted by practical mining engineers, they must be convinced that it can compete economically with other methods of transmitting energy which are well known and generally applied. What percentage of indicated steam power applied to the generating electric machine is given off ultimately as available energy for mechanical work? How does it compare as to cost? Under what circumstances would its application be economical? If questions such as these can be plainly and satisfactorily answered, practical men will not be long in arriving at a favourable opinion and acting upon it.

The application of electricity to underground pumping has enabled the writer to tabulate some particulars which he believes will go a long way towards satisfying inquiries that this is a method of transmitting energy capable of wide and economical adaptation.

Some four years ago Mr. W. B. Brain described to this institute, in a short paper, a small electric pumping plant at Trafalgar Colliery, Forest of Dean, doing the work of about 1½ horse-power. This, the writer believes, was the first attempt ever made at pumping in mines by electricity. It has continued working satisfactorily up to the present time. A similar set, using about 2½ horse-power, has been working in another part of the mine, some 800 yards from the surface, for the past one and a-half year. Both are doing excellent service, removing small quantities of water from remote parts of abandoned workings, which, for the safe working of the colliery, must be kept free from accumulations of water. It may be well to say the majority of the collieries in the Forest of Dean have their shafts sunk on the "rise" of the taking, and the coal is won by "dipples," or engine planes, going full dip with the strata. The outcrop is riddled with old abandoned workings. These receive a great quantity of surface water, which finds its way down the slope of the strata to the deeper workings now in operation. The two electric pumps above referred to intercept some of this water on its downward course. The electrical pumping plant which the writer purposes describing in this paper has been put in to deal with the main come of water in the deep workings of the Trafalgar Colliery. The pump and motor are placed a distance of about 1,650 yards from the bottom of the shafts, and the water has to be forced by this pump a vertical height of 300ft. to the pit bottom. This water had previous to May last been coped with by one of Hathorn-Davey's water-power pumps, working in conjunction with a 7in. double plunger Manchester Pearn pump, with 10in. steam cylinders and 14in. stroke, the steam being obtained from the tubular boilers fixed underground.

The present pump—a double 9in. plunger with 10in. stroke—has been specially designed by the Lilleshall Iron Company (Limited) from sketches furnished by the writer, and is fitted with spur gearing running six to one. It is driven by a leather link belt, running off a 5ft. 9in. pulley, keyed on the same shaft as the spur pinion to a 14in. pulley on motor shaft. Thus, when the motor is running at about 650 revolutions per minute the pump is making 25 revolutions. The motor, supplied by Elwell-Parker, of Wolverhampton, is described as one of their 12in. machines—maximum speed about 650 revolutions per minute, output about 13,000 watts. The electric current is conveyed to it by a copper cable 2,000 yards long 19/16 wires, wrapped with compounded tape, and was supplied by the India Rubber, Gutta Percha, and Telegraph Works Company, Silvertown. This is enclosed in wooden boxes in the pit shaft only. It is supported upon earthenware insulators, placed at intervals of about 10 yards along the side of the underground roads. The return cable is an old iron pit rope about 4in. in circumference stapled to the road posts. The generator, placed on surface near the top of the shaft, is another of Elwell-Parker's 12in. machines. Its maximum speed is about 950, and output 17,000 watts. A belt communicates the power from a 12in. pulley on the generator to a 5ft. 11in. pulley attached to the crank shaft of an engine. The steam engine has a single 16in. cylinder with 12in. stroke, and works with about 35lb. steam pressure.

It is an old marine engine, picked up some time since at an auction sale, and is not what one would purchase new for the work. It indicated running empty a loss of 5 horse-power, the valves and piston being both the worse for wear. In the same engine house is another engine, which supplies the power for the two small electric pumps previously referred to. The steam for both is obtained from the range of colliery boilers near. A small insulated copper wire connected to a battery of eight No. 3 Leclanché cells connects the engine house with the pump house underground, and through this is registered upon a belt in the former each stroke of the pump. It is also used as a telephone line, so that a conversation can at any time be carried on between the engine-man on the surface and the man in charge of the pump underground. The two smaller pumps are locked up, with no one in charge, only being

* Paper read before the South Wales Society of Engineers, Cardiff, 24th November, 1887.

Digitized by Google

visited occasionally; but with the larger one someone is thought necessary, although there is rarely anything more to be done than oil the machinery, adjust the machine brushes, and turn on the current. Near the engine the necessary electrical instruments, a voltmeter and an ammeter, are placed, by which the engineman knows the machines and cables are working properly. A magnetic cut-out is also placed in the main circuit, so that should the current through any unforeseen cause increase, it automatically breaks the circuit, thus preventing the flow of electricity through the cables. The maximum speed at which the pump has been driven is twenty-five strokes (114 gallons) per minute. The observations taken at the time were:—

Indicated horse-power of steam-engine	29·49
Speed of generator	900
Volts (at terminals of generator)	320
Amperes ,, ,,	43
Speed of motor	650
Volts (at terminals of motor)	260
Amperes ,, ,,	43
Actual horse-power of water lifted	10·36

The first diagram exhibited is prepared from the above figures, and shows the total loss of power—19·13 horse-power—to be apportioned thus:—

Loss in engine	6·49 horse-power,	or 22 per cent.
Loss in generator	4·56 ,,	or 16 ,, ,,
Loss in line	3·45 ,,	or 11 ,, ,,
Loss in motor	3·00 ,,	or 10 ,, ,,
Loss in pump	1·63 ,,	or 6 ,, ,,
	19·13	65 per cent.

The actual proportion of power given off by steam engine used to lift water is therefore 35 per cent. A second diagram shows the percentage of useful effect extracted from the power received at each stage, together with the percentage of loss—thus, horse-power indicated by steam engine 29·49:—

			Per cent.	Useful effect. Per c.
Received by generator	23·00 h.-p.,	loss in steam engine	22	78
,, cables	18·44 ,,	,, generator	20	80
,, motor	14·99 ,,	,, cables	20	80
,, pump	11·99 ,,	,, motor	20	80
,, water	10·36 ,,	,, pump	14	86

A third diagram shows the loss between the power given off at the belt of the steam engine and the actual work done, thus:—

Horse-power given off to generator		23·00	
Loss in generator	4·56 horse power, or 20 per cent.	20	55%
Loss in cables	3·45 ,, ,, ,,	15	
Loss in motor	3·00 ,, ,, ,,	13	
Loss in pump	1·63 ,, ,, ,,	7	

The proportion of power given off by belt used to lift water is therefore 45 per cent. As to cost, the writer has been to considerable pains to verify the following figures, knowing that with business men this is the crucial test. The following is a summary of the first cost of the plant:—

	£	s.	d.
Two electric machines	£310	0	0
Insulated copper lead	138	0	0
Return wire-iron rope	25	0	0
Signal wire	10	0	0
Insulators	6	0	0
Steam engine (estimate)	140	0	0
Fixing and sundries	15	0	0
	£644	0	0

The pump (£130) and pipes are not added to the above, seeing this item of cost would of necessity be part of any set of plant, and it would therefore be an item of cost common to all systems.

Detailed cost of pumping 114 gallons per minute with above machinery through 1,300 yards 7in. pipes, main rising 300ft., one week's pumping, 22 hours per day:—

	£	s.	d.
Engineers (half-time)	£1	8	0
Man underground (full time)	2	9	0
Small coal consumed, say 36 tons at 1s.	1	16	0
Oil, waste, and sundries	0	7	0
Say 15 per cent.	1	17	0
	£7	17	0

Cost per horse-power on water raised, 0·2 of a penny. Cost per 1,000 gallons of water raised, 1·80 pence.

The come of water in the deep workings of the colliery has been much below the average during the past dry autumn. The pump has therefore been usually worked at about 64 gallons per minute. The results, of course, not being so good, are as follows:—

Proportion of power generated used to lift water, 32 per cent.; cost per horse-power in water raised, 0·3 of a penny; cost per 1,000 gallons of water raised, 3d. When opportunity offers and the hold of water is pumped out this plant is utilised to assist in maintaining the ventilation. Some 1,200 yards underground a small fan, passing some 10,000 cubic feet of air per minute, is placed in a return air way. A branch connection is made from the main cable to an electric motor, which drives the fan by belt connection. The cost of maintaining the present plant, compared with that it has supplanted, shows an economy of about £470 per annum. This, the writer does not, however, rely upon as a fair comparison of cost, seeing that the former plant had to be worked under most disadvantageous circumstances.

The whole of this plant was supplied by the various makers to specification, and was put in by the colliery mechanics without any outside assistance. It commenced working without a single hitch, and has worked continuously since the end of May last with but one accident. This, strictly speaking, cannot be spoken of as an accident. A couple of weeks ago, we found much more current was being taken to do the ordinary work than usual, and on examination traced the cause to the cable in the pit shaft.

Here, as already explained, the cables, which are not highly insulated, are carried in wooden troughs. The late continuous heavy rains had very much increased the feeders of water in the shaft, and this water, finding its way into the boxes, saturated the cables, causing a great escape of current. A lead-covered cable was substituted for the ordinary one, and the difficulty was completely overcome.

The cable was a matter of some anxiety when the plant was being provided, as the writer feared that falls, which cannot be prevented on underground roads, would be constantly damaging it and causing delays. In practice, this has never yet been found to occur. With the one line indestructible (as the iron pit rope practically is) the other, should it be damaged, can quickly and easily be repaired, or replaced with new, so that this, one of the most formidable of the anticipated, difficulties has proved quite illusory. The plan which has been adopted of supporting the cable upon earthenware insulators has proved a good one, more perfect insulation—a very important factor—being obtained. The repairs necessary to the side timber of the roads along which the cables are suspended is also facilitated.

The commutators are the principal electrical wearing parts, and with care these will run a considerable time. In this instance, after five months' work, the wear shown is only about one-sixteenth of an inch, although there is an inch thickness of copper to be worn away before it is necessary to have a new one. With a spare armature kept in hand, which costs about one-third the price of a machine, no accident can happen which the colliery mechanics cannot repair, and that with little delay, everything being simple in construction and easily to be got at.

It is an advantage which colliery managers will appreciate to concentrate work and have it under personal supervision. Given sufficient engine power, any reasonable number of generators can be driven in one engine house on surface, delivering power to distant places underground at various points of the compass. These dynamos would require but one man to attend to them, and the work done could with ease be supervised. The steam, too, can be generated at least possible cost under such circumstances, and with the work divided between two or three engines a breakdown with either—should it occur—need not cause any delay. It is especially noticeable that this plant can be put down economically and with great despatch. With pipes carrying steam-compressed air or water it is often necessary to place them in ditches specially made at considerable expense along the sides of the underground roads, so as to protect them from injury and keep them out of the way.

The outlay in pipes is also great, more especially when the route is devious, and if the roads are at all given to "puck" these are constantly being broken. With electric cables none of these difficulties occur. No matter how intricate the route may be a thousand or two thousand yards can be put to work in as many hours as it would require weeks to put in pipes. Given a pump with the necessary suction and delivery pipes fixed a mile underground, with steam power available on the surface, it would be practicable to have that pump in work in less than a week, an impossibility with any other method. The drawing attached gives a side view of the generator in the surface engine house and of the motor and pump in the underground engine-house, together with a plan of the latter. Another one shows the method of suspending the cables.

A few brief extracts from papers already put, tested, comparing the cost of electricity with the power derived from steam, compressed air, or hydraulics may be interesting.

The following is given by Prof. Schulz* (*Proceedings* Institute Civil Engineers, Vol. LXXVIII., page 67, and *Transactions* North of England Institute of Engineers, Vol. XXXIV., page 5.

A comparison between electric transmission and mechanical methods was published in Berlin in 1883 by A. Beringer,* and awarded a prize by the Electro-Technical Society there.

A *résumé* of it appears in the *Revue Universelle des Mines* (Series 2, Vol. XV., p. 522). The following brief extract may be of interest:—

Comparison of cost on 10 effective horse-power-hours transmitted 1,093 yards.

By cables	1·77	pence per effective horse-power per hour.
By electricity	2·21	,, ,, ,, ,,
By hydraulics	2·90	,, ,, ,, ,,
By compressed air	2·98	,, ,, ,, ,,

Comparison of cost on 50 effective horse-power-hours transmitted same distance.

By cables	1·35	pence per effective horse-power per hour.
By hydraulics	1·87	,, ,, ,, ,,
By electricity	2·07	,, ,, ,, ,,
By compressed air	2·27	,, ,, ,, ,,

Comparison of cost on 10 effective horse-power-hours transmitted 5,465 yards.

By electricity	2·64	pence per effective horse-power per hour.
By compressed air	4·66	,, ,, ,, ,,
By cables	4·69	,, ,, ,, ,,
By hydraulics	5·29	,, ,, ,, ,,

Comparison of cost on 50 effective horse-power-hours transmitted 5,465 yards.

By electricity	2·37	pence per effective horse-power per hour.
By cables	2·65	,, ,, ,, ,,
By compressed air	2·99	,, ,, ,, ,,
By hydraulics	3·02	,, ,, ,, ,,

Steam was the prime motor used in each instance.

From the above figures it is inferred that for distances of about 1,000 yards cable transmission costs least, but that in longer distances electricity takes the lead and maintains it against all other systems.

The cost per effective horse-power per hour of the electrical pumping plant herein described is found by the figures as to cost already given to be 1·18 pence. It is obvious a future is before electricity in the transmission of power. For coal cutting it affords a ready means of distributing power, for hauling engines, which can either be stationary or run to various parts of the colliery on prepared tracks, as well as in pumping; this new motive power must take a place, and that no despicable one, in the future of colliery working.

* See *Electrician*, April 1st, 1887.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *Dec. 1st*, 1887.

It may perhaps be remembered by your readers that quite a sensation was created recently by the granting of certain telephonic and other concessions in China to a syndicate of American capitalists. Steps have recently been taken to exploit and improve the concession granted, and it is said that a large amount of American capital is likely to become invested in this way in supplying the inhabitants of the Celestial kingdom with telephones and other conveniences of modern civilisation. It has been understood here that the award of this concession has awakened various English and foreign jealousies. It may also be said to have aroused cupidity here at home.

Mr. Chester Holcomb, of Pekin, at one time attached to the American Legation there, is now in Chicago, and he claims to hold valuable Imperial letters patent, in comparison with which the Mitkiewicz grants sink into insignificance; in fact, he goes so far as to say that Count Mitkiewicz holds nothing but a memorandum drawn up by some Government underling. However this may be, Mr. Holcomb and his friends propose to proceed at once to the development of Chinese resources.

The question of Government control of the telegraph is steadily coming to the front, and it promises to be ere long a prominent political issue. It may even have some bearing on the Presidential campaign next year. The Senators and Representatives now assembling in Washington for the next Congress betray a lively interest in the subject, seeking information in every quarter, and many of them come armed with Bills and legislative projects dealing with the subject. More than this, the Knights of Labour have taken a hand in the matter, and are said to favour Government control well nigh unanimously. Mr. T. V. Powderley, the General Master Workman of the Order, is giving no small amount of attention to the question, and has been in New York this week securing all the data available on it, including English blue books and official documents. He has also been in consultation with Mr. T. O'Reilly, who is at the head of the brotherhood of operators in this country. Mr. Powderley says that his Order is determined to put forth all its energies in this direction, so that if possible the desired change may become an accomplished fact during the next Session of Congress. The details of the scheme that the Knights of Labour are likely to favour have not been published. If the Knights stand with the Brotherhood they are hardly likely to propose to buy out the Western Union Company, and yet some such course would seem necessary if steps are taken to put an end to private ownership of telegraphs.

The rigour of our American winters, when the ground becomes as hard as a rock at a depth of several feet, prevents any furtherance of subway work until the return of spring. You have already made note of what has been accomplished in this city by the Board of Electrical Control in burying the wires, and the Board has certainly done a good deal of work; but it is said that the past year has actually seen an increase in the quantity of overhead wires, so rapid has been the extension of various services in the newer districts. One of the most important features of the work done during the past autumn has been the preparation of a very large section of uptown New York, including most of the finest hotels, restaurants, theatres, churches, public halls, and private residences, for service from the Edison system. The district is bounded by 18th and 59th-streets, and by 3rd and 8th-avenues. At a rough guess this district accommodates a population of about half a million, and is at present the most wealthy and respectable portion of the city. In this territory the Edison Company will have three stations. The first of these is already under construction in 26th-street, near 6th-avenue, and it will be in operation by the beginning of the year. It will be a notable building in many respects, handsome though not too ornate, but in every way massive and safe. As far as can be now learned, no provision is made for storage batteries to supplement the plant, but special pains have been taken to secure several hours' reserve of both coal and water. It may be mentioned that the boilers and engines are at the top of the building, and that coal and water will be stored above them. The station will be equipped with a new form of Edison dynamo, and an improved type of Armington and Sims engine. This station will have a capacity of 30,000 lights. When all three stations are in full blast, as they undoubtedly will be in the near future, they will feed at least 100,000 Edison lamps, and the district will be wired up for at least 170,000. It will thus be seen that in New York, at least, we are rapidly approaching the time when electricity is to gain its rightful position as the best means of interior and domestic illumination. It should be added that within this large district a considerable quantity of electric power will be distributed from these stations in the day time by Sprague motors.

Great improvements have been made in this country of late years in the manufacture of wire for electrical purposes. Some

Digitized by Google

remarkable developments have been attained of late with silicon-bronze wire. I saw this week a sample of this wire made by the Scorill Manufacturing Company, of Waterbury, which had withstood a twisting test of over 100 turns in six inches. I believe silicon bronze wire already enjoys considerable vogue in Europe. It now promises to command a place of its own in America.

Few things have been more remarkable than the extraordinary rate at which the alternating current system of electric lighting has been introduced and put in operation in all parts of the United States. There is hardly anything to compare with it. The Westinghouse Company has been making contracts for plants of this system at the rate of about 20,000 or 30,000 lights a month, and the demand seems to grow rather than to fall off. With so rapid a rate of introduction it is but natural that some careless work in wiring should be done, and as a result there have been several accidents in the use of the system. How far these are due to the inherent defects and dangers of the system, or may be ascribed to careless work in insulation, continues to be a matter of lively dispute. Meantime this rapid commercial development has stimulated interest in the scientific questions connected with the subject, and whatever literature exists with regard to it is read with great avidity. Mr. William Stanley, jun., electrician to the Westinghouse Company, has for two or three years been devoting his attention almost exclusively to a study of the alternating current and its phenomena, and he intends to bring some results of his investigations before the American Institute of Electrical Engineers next week.

It has been very gratifying to all well-wishers of the electric light to see that so extensive a plant has been put in operation at Leamington. It is regarded here as of the brightest augury that so shrewd and representative a family as that of the Chamberlains should be actively represented in the enterprise. It is hoped that the work may not stop at Leamington, but that that city may simply serve as the turning point in the tide. It is thought a little singular that the gas companies in England have as yet shown so little desire to concern themselves with electric light supply. In America the tendency is so markedly in the other direction that it is safe to predict that the vast majority of gas companies in this country will before 1890 be operating electric light plants, both arc and incandescent.

CORRESPONDENCE.

DISEASES OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of December 2nd I notice that Prof. S. P. Thompson is reported to have said that "unequal fields were often the cause of sparking, and on this account double magnets had an advantage," and in your issue of December 9th Mr. W. B. Esson, in his letter on the above subject, mentioned the fact that in single horseshoe field-magnets more lines go through that half of the armature nearest to the yoke than through the farther half. He then goes on to suggest a means of equalising the flow of lines in the single circuit machines.

These statements inferentially cast a stigma on the single horseshoe field-magnet which is by no means deserved. Sparking at the brushes is no more likely to occur in a machine with a single horseshoe field than in one having a double field. The current being collected from the armature coils by a brush will not cause sparking provided that lines of force are being cut by the coil at the time when it passes under the brush, such number of lines being just sufficient to neutralise the E.M.F. of self-induction in the coil caused by the reversal of the current which it is carrying. In a double horseshoe field the amount of lead at which all sparking ceases at one brush will be approximately correct for the other brush; but in a single horseshoe field (inverted Edison field) the upper brush will require rather more lead than the lower—that is all. Both types of field are equally good if the brushes are properly adjusted as regards non-sparking. And in other respects the single horseshoe machine offers some advantages. The current idea that the brushes of *all* machines should be set on a diameter is fallacious; obviously, the brushes of machines having ring armatures should be set independently.—Yours, &c.,
J. G. STATTER.

West Drayton, December 14, 1887.

PRIMARY BATTERIES FOR HOUSE LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. N. G. Thompson has supplied you with a table intended to show the comparative cost of engine power and primary batteries; but, as regards the latter, he has been unfortunately misled by the figures as reported in Mr. Nursey's paper, upon which he founds his calculations, and a more careful examination of those figures will alone require him to decrease his estimate of the cost of a battery by nearly one half. Should he so examine them, he will perceive that ten 10-candle lamps of 30 watts each, burning for 20 hours, represent 6,000 watts, or rather more than eight electrical horse-power-hours instead of five, over which to spread the cost of the liquids used during that time; and again, he will hardly need to be reminded that the cost of the outer (or zinc) liquid, once incurred, does not need to be repeated every 20 hours, nor even every 20 weeks, so that it may be taken as so mere a fraction of a farthing per horse-power-hour that it can safely be eliminated from the estimate.

Following, then, Mr. Nursey's figures, this reduces the cost of the "fuel" to 6d. for the zinc (which is taken at 50 per cent. above its wholesale price) and 6¾d. for the liquids, or a total of 12·75d. per horse-power-hour, instead of the 20·40d. inserted in Mr. Thompson's column under the heading of the "working cost of battery."

He errs equally in the opposite direction as regards the cost of a dynamo and engine for small installations, which is ground so shifting that upon it even angels would fear to tread. Their average cost, as given in the parallel column, is estimated at about 1s. per horse-power-hour when coal or gas is supplied to an engine for five hours daily, or 1s. 6d. when they are supplied for three hours daily. But these figures merely cover the wages at 30s. a week of one engine driver and the cost of the fuel used during those hours, which is not by any means the same thing as keeping the lamps lighted—as in his estimate of the battery cost—during the same number of hours, for neither is steam got up instantaneously wherewith to work an engine, nor can a gas-engine be used for the supply of a steady current to 24 incandescent lamps without intermediate accumulators requiring further time to charge them. Moreover, the installation in the cellar of a private house of engines and dynamos, generally involves expensive foundation works, &c., and nothing is put down for the annual interest on capital, for wear and tear, or for the frequent renewal of brushes.

In a recent instance with which I am acquainted, as much as £900 has been expended on the installation in London of a very unsatisfying 2 horse-power gas-engine and the corresponding dynamo and accumulators, where equal or superior battery efficiency would have been attained at a cost of £100.—Yours, &c.,
O. C. D. ROSS.

P.S.—Four shillings per week for labour is excessive with such a battery as I described at the meeting of the Society of Engineers, in which all the cells "feed themselves" from surrounding liquid.

THE CONDUCTIVITY OF GLASS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I do not wish to enter into any personal controversy with Mr. Proctor, but after his letter published in your last week's issue I must ask you to permit me to add one or two observations.

Mr. Proctor will no doubt recollect that I was always perfectly free and open with him in the discussion of any experimental work on hand, and I have no doubt he remembers as

Digitized by Google

well as I do how he aided me in carrying out the experiments to which I referred.

We freely discussed every part of the question together, but I certainly have no recollection that it was he who *first* suggested to me that the blackening was due to electrolytic action, or I should have attributed the observation to him.

It was one of the pump hands who first pointed out the persistency with which the blackening occurred on one side, and this observation it was which really gave the clue to the whole matter.

In writing my note on the subject, I was careful to word it so as not to claim for myself any credit that I did not consider belonged to me, but I do not think in writing a simple note on a scientific subject you want the whole history of the development of the idea; though if there is any special credit due to Mr. Proctor, I am sorry not to have given it to him. Mr. Stearn's reply to Mr. Proctor's letter, however, appears to indicate that, at a time when he (Mr. Proctor) was supposed to be aiding me, and when the whole matter was a frequent subject of conversation and free comment between us, he was writing, unknown to me, to our superior officer and calmly claiming the entire credit of the observations for himself!—Yours, &c., NELSON K. CHERRILL.

AN INQUIRY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you or any of your readers kindly tell me of any means by which I can obtain an instantaneous electrical contact from the sun, so that I can get solar time any day?—Yours, &c., W. HARDY, JUN.

Mistleton, Oakham, Dec. 10, 1887.

PHYSICAL SOCIETY.

At the meeting of the Physical Society on the 10th inst., Dr. R. C. Shettle read a paper entitled "Rotation of a Copper Sphere and of Copper Wire Helices when Freely Suspended in a Magnetic Field."

The experiments shown were of a novel character, and excited considerable interest. A copper sphere was suspended close to the pole of an electro-magnet, and when the magnet was excited it slowly turned through a considerable angle, and ultimately came to rest, returning to its original position—determined by the torsion of the suspending fibre—when the current was turned off. The direction of motion was independent of the direction of the current.

Dr. HOFFORD, who had seen Dr. Shettle's experiments the day before, devised an experiment in illustration of the same action, which he exhibited to the society. He suspended a copper disc, punched out of a sheet of copper, in a horizontal position between the poles of an electro-magnet. When the magnet was excited a deflection was found to take place which, as in Dr. Shettle's experiments, was independent of the direction of the current. Dr. Hofford also found that within the limits of a hastily-devised experiment the deflection was not appreciably affected by removing one of the pole-pieces of the magnet. The effect cannot be due to induced currents in the copper, since the deflection is permanent with a steady current. Dr. Hofford was inclined to attribute it to dia-magnetic action, due to want of homogeneity in the copper. It might also be due to the presence of iron or its magnetic equivalent in the copper. Which of these two explanations is the correct one may easily be decided by allowing the metal to oscillate in presence of the excited magnet, and determining the logarithmic decrement, which would decide whether or no the effect was due to induced magnetisation.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

ANNUAL GENERAL MEETING, DECEMBER 9.

The annual report read and adopted at this meeting, besides announcing the award of prizes to Messrs. Kennelly, Sumpner, and Fleetwood, as reported in our last issue, went on to state that the several committees of the Society having under consideration the subjects of electrical nomenclature, the formation of a standardising laboratory, and a revision of the rules relating to fire risks, were approaching the completion of their labours, and that their reports would probably appear very shortly. A noticeable increase in the number of students was a matter for congratulation, and the Society had determined that the papers read at the Students' Meetings should be eligible for the prizes at the Council's disposal, the same as papers read before the Society's ordinary meetings. Subscriptions invited towards the Imperial Institute had amounted to £71. The Jubilee Fund for the improvement of the Society's library had now reached £172. The hon. secretaryship, vacant by the decease of Colonel Frank Bolton, was not to be filled; and in future the duties of Mr. Frost, the late librarian, also deceased, would be performed by the Society's secretary, Mr. F. H. Webb. The Council had under consideration the advisability of changing the title of the Society, and were of opinion that the "Institution of Electrical Engineers" would, in the changed circumstances and the time, be a fitter title than the one borne by the Society at present. This matter will, however, be submitted to the members before any decisive steps are taken.

After the usual votes of thanks to the Institution of Civil Engineers for the continued use of their theatre, and the foreign hon. secs., the hon. treasurer, and solicitor, a paper was read by Mr. A. C. COCKBURN, F.C.S., on "Safety Fuses for Electric Light Circuits, and on the Fusing Points of Various Metals Employed in Their Construction." The paper was profusely illustrated by diagrams and apparatus, many experiments with various kinds of fuses being shown in the course of the evening.

We hope to give a full report of this paper in due course.

DISCUSSION ON MEASURING INSTRUMENTS AT THE SOCIETY OF TELEGRAPH-ENGINEERS.

(Concluded from page 112.)

Mr. SWINBURNE said they were all very glad Dr. Fleming and Mr. Gimingham had brought out their instrument, chiefly because it would be most carefully calibrated. As a rule bad calibration was the weak point of an instrument, more than bad design or bad construction. The first thing in the way of criticism that struck one in that instrument was the method of bringing in the current. He had tried wattmeters with two springs, pivoted, one to bring in the current and the other to bring it out again, and he might say he could find no trouble in it. The current was necessarily small, and the surface of the springs was very large. He did not know anything about the temperature coefficient of springs, but taking the percentage of error in the watch it was not very great; it was too small to affect an instrument of that sort. Another thing in looking at that instrument which struck one was the ingenious way in which coils were brought into a state of equilibrium. Those who had spent time in designing instruments in which large force was required for small expenditure of energy, had found that nearly all the methods which struck one had coils in a state of unstable equilibrium. He was glad to see the spring was used again in instruments, and he would also like to see the prejudice against permanent magnets removed. The advantages of using them were so great that they ought to come into general use. He did not know whether Dr. Fleming proposed to use his instrument for alternating currents. Coming to Profs. Ayrton and Perry's instrument, he always went for Prof. Ayrton whenever he got a chance, partly on principle, and partly because he liked it (laughter). He thought everybody would like to have discovered the heated wire of Capt. Cardew, and everybody wished very much indeed that he had invented that spiral spring arrangement, for with the two things combined they seemed to get perfection (hear, hear).

Colonel ARMSTRONG asked the effect of external changes of temperature on the instruments. He would also like to know to what extent they had been used, and with what degree of accuracy they worked.

Captain SANKEY asked Prof. Ayrton what kind of fuse he used.

Mr. GUMPEL was of opinion that Dr. Fleming's instrument was not the instrument of the future for general use or for the workshop. He would like to ask Prof. Ayrton what influence repeated tension or contraction of the platinoid wire against the spring had on the accuracy of the instrument.

After a few words from Mr. GIMINGHAM, Mr. GISBERT KAPP, and Mr. SPAGNOLETTI,

Dr. FLEMING replied: He expressed his and Mr. Gimingham's sincere thanks for the kind way in which the paper had been received and for the valuable criticisms which had been passed. He agreed entirely with a great many things Mr. Gordon had said on the last occasion. One of the most pressing wants was a really good engine room voltmeter, one that could be seen across a large room. The instrument they had brought forward was of the same type as that of Mr. Siemens. The principle was not new, and the first person to arrange an electro-dynamometer was Weber, about 1846. He was very glad to see the instrument designed by Sir W. Thomson on the table. They had one of his standard current meters in their laboratory, and they used it constantly. It was a very beautiful instrument, and it could not but be so when they recollected the immense ingenuity and wonderful theoretical knowledge which Sir W. Thomson brought to bear on all that he did. At the same time it could not be denied that the instruments were not convenient as portable standards. They required very careful arranging, and he (Dr. Fleming) used them as standards for checking other instruments. He endorsed the remarks that it would be difficult to get a reading if the current was in the slightest degree unsteady. With respect to the

Digitized by Google

effect of the current on the elasticity of the spring, the objections raised seemed to be formidable in theory, but they did not turn out to be very great difficulties in practice. They had tested the instruments by keeping the current on them for some time, and they had found that when the instrument had been kept on the circuit for some time there was no alteration of reading due to the change in the elasticity of the spring within the limits in which the instruments were intended to read. He was very glad to hear Mr. Evershed's remarks, because they all knew that he had paid very great attention to the manufacture of electrical measuring instruments. He agreed that the instrument by being wound partly with copper and partly with platinoid might be made to take less power. One reason why German silver was used was to reduce the variation coefficient. Mr. Swinburne mentioned the fact of mutual induction between the currents increasing the self-induction of the instrument on the whole, and therefore it was not available for measuring alternating currents. The instrument was not put forward as meant for measuring alternating currents. Colonel Armstrong had asked to what degree of accuracy these instruments could be depended upon. The object which they had in view in designing the instrument was to make a portable standard which should be free from the objections which exist in instruments in which iron was used. It was possible to take a reading in the neighbourhood of 100 volts to about a quarter of a volt, or perhaps a little less; and the instruments were intended to be sensible within one part in four or five hundred, in that part of the scale which presumably they will be most used. Replying to Mr. Spagnoletti, he said the instruments had not been in the hands of the public but they had been thoroughly tested, and they were satisfied they had a portable and convenient form of electro-dynamometer, which was portable in this way—that there were no mercury cups to be filled, which were considerable objections. Although the instrument would not be used for marine purposes, or where a perfectly steady table cannot be secured, he thought they would be able to get over that objection by producing an instrument which would be free from any necessity of levelling. Dr. Fleming concluded his reply with some criticisms upon the instrument produced by Profs. Ayrton and Perry.

Prof. AYRTON said reference was not made in the paper to the extremely interesting instrument that Sir Wm. Siemens had introduced, and the reason why was that, although it was an instrument for the measuring of current, they did not wish, as they were using Captain Cardew's voltmeter principle, in any way to imply that Captain Cardew had been anticipated, or to detract in any way from the credit due to him for having used this principle for the measurement of volts. He had referred to the information supplied by Captain Cardew, and he thought of using the sag of the wire for the purpose of measuring volts, but, as he himself had said, without some such arrangement as the magnifying spring, it was impossible to use the principle for making commercial instruments. He was inclined to agree with Mr. Swinburne that such instruments as had been exhibited by Dr. Fleming could not be called direct reading instruments, and he thought the name should be kept for instruments in which the hands pointed to the reading exactly in the same way as a clock indicated the time. He was inclined to agree with Mr. Esson as to the wattmeter, and he thought that he had some right to criticise the wattmeter, because the first made in this country was made by his colleague and himself, and it was rather interesting how it was made public. There were two papers down for reading at the British Association in 1881, one by Sir William Thomson and the other by himself and Mr. Perry. As a matter of fact their paper came first, and Sir William Thomson's second, in the printed list. Sir William Thomson told them he had to go to a committee meeting, and asked if they had any objection to his reading his paper first. He described the principle of the wattmeter, and when their turn came Sir W. Thomson, chairman, called on them to read their paper. He (Mr. Ayrton) told him he had already read it, and there was the instrument which illustrated what he had said. He (Sir Wm. Thomson) had priority in reading the paper, and they had priority in producing the instrument. He had had no experience of Sir W. Thomson's current meter on the table, but like all his instruments it was no doubt extremely beautiful and accurate; but such instruments as these aimed at obtaining a totally different sort of results from those which they (Profs. Ayrton and Perry) had from time to time brought before the society. There was the same difference between that instrument and others on the table as there was between the astronomical clock at Greenwich and the watches they carried in their pockets. With reference to the question about the fuse wire, 0·4 mills, the finest wire they had used for the expanding wire in their voltmeters was 1·4 mills, while in some instruments it was 2 mills. Now, although this was much finer than the wire Captain Cardew employed generally in his voltmeters, viz., 2·5 mills, it was nevertheless much thicker than fuse wire, so that there was no difficulty on that head.

The PRESIDENT (interrupting): Can you use that form of dynamometer on board an electrical launch?

Prof. AYRTON: Certainly.

The PRESIDENT: In any kind of weather?

Prof. AYRTON: Yes. In any kind of weather, fair or rough, provided you do not suffer from *mal de mer* (laughter). Any weather suitable for yachting is suitable for that instrument. Captain Cardew, like many others, had suffered a great deal from the want of knowledge of the instrument makers, and he did not know that any of the instruments made had done him any particular amount of credit. On the matter of calibration a number of experiments were being carried out, and it was for that reason they had not introduced the compensation—which was quite easy to introduce. In order to introduce that compensation with certainty they required to know this fact: What is exactly the coefficient expansion of the platinoid silver under considerable tension? That acquired, there was not the slightest difficulty in compensating one of these instruments. Experiments had been made with the instruments. The wires had been warmed up many degrees centigrade, and they knew exactly the change of zero and of sensibility with temperature. The change at zero was about half a degree, or one degree. That was very small. In one instrument there was no change of sensibility. What they wanted to know was the exact coefficient of expansion of platinum silver with temperature, and when they had got that it was a mere question of calculation. As they would observe, instruments had been placed vertically instead of horizontally. A great deal had been said about the pointers not being visible enough; but people forgot that a watch was a very useful instrument, despite the fact that they could not see the hands at forty yards distance. Mr. Evershed had raised some interesting points as to the power expended with different wires, and to these and other questions raised he would reply in his written answer. At the last meeting an impression might have been introduced in the minds of some that he had brought an old specimen of the Cardew voltmeter with the idea of disparaging Captain Cardew's voltmeter. Nothing was further from his mind. He was under the impression that he was bringing a new form. He bought it as a new form. It had taken many months to make, had cost a lot of money, and had been sold to him as the most improved form of Cardew voltmeter.

On the motion of the Chairman, a cordial vote of thanks was passed to the authors of the paper.

THE BRADFORD CORPORATION AND THE ELECTRIC LIGHT.

At a meeting of the Corporation of Bradford, held on Tuesday last, a report of the Gas Committee came up for consideration, containing a recommendation to the Council to provide an installation for electric lighting in the borough over a certain area, at an estimated cost not exceeding £15,000.

Alderman F. PRIESTMAN moved the adoption of the minutes. He said he did not think it would be necessary for him to occupy much time, because this question was by no means a new one, and had been before the Council on different occasions during the last four or five years, but more particularly, perhaps, during the last twelve or eighteen months. He did not expect that any member of the Council would either think or say that the Gas Committee had brought this question forward with undue haste. He did not think that the delay which had occurred was by any means lost time, because without doubt a very important improvement had taken place in machinery for the generation of electricity, while in the matter of distribution the work was much better done now than was the case a few years ago. The Council might therefore with confidence spend its money with the certainty not only that the undertaking would be of a more permanent character, but that it would be more remunerative than would have been the case twelve months ago. Members of the Council would remember that in 1883—when electric lighting stood very high in public favour, and when companies were being formed not only in London but in almost every county of England, and when the shares of such companies went up to an enormous premium, and those of gas undertakings were correspondingly depressed—the Bradford Corporation went to London to resist an application on the part of a London company to supply Bradford with electricity, and at the same time they (the Corporation) went to London for a Provisional Order to give them the right to put down electric light in the borough. In both these applications the Corporation were successful. This order was still in force, and by a subsequent Act of Parliament the Corporation had very large powers conferred upon them. They had power to prevent any company from carrying their wires over any of the streets, so that at the present time they had absolute power to keep other companies out, and practically to do what they liked themselves. But these powers were granted to the Corporation on the understanding that they would be used, and they were not intended merely as a shield to prevent competition unless the Corporation did something—not intended, in fact, that they should refuse to allow any one to put down electric light, and at the same time to refuse to do it themselves. On the contrary, it was distinctly stated in their Provisional Order that if the Corporation vexatiously deferred taking action in the matter the powers might be granted to other persons. The committee thought the time had come when the Corporation must either do the work itself or grant powers to others, and he did not think there would be two opinions in the Council as to which was the better course. Alderman Priestman then went on to say that Messrs. Schmidt, Douglas and Co. (who have a small central station already at work in Bradford) had made overtures to the committee with regard to the purchase of their plant; but for various reasons, which were given at length, the committee were unable to recommend the Council to take this step. After the negotiations with them, the committee felt that they had no longer any alternative but to recommend the Council to put down an installation of their own. Although they asked for £15,000, it was not their intention to spend at the present time more than from £8,000 to £10,000. The winter months were

Digitized by Google

already partly gone, and it was quite impossible to put down an installation for the whole of the town which would be of any use during the present winter. If, therefore, the Council sanctioned the expenditure proposed, the committee would put down a small installation, and test it during the spring and summer, afterwards applying to the Council for further powers if they thought it necessary to do so. Their plan was briefly this: They would erect a boiler house and an engine and dynamo house on land belonging to the Corporation in Holdsworth-street. They proposed to put down two or else three 150 horse-power engines, either compound or triple expansion, with dynamos of course sufficient for the power required. Their present intention was also to lay down two main cables—one along Market-street as far as the Town Hall, and the other up Kirkgate and Darley-street as far as the markets and the free library. The cables would be laid underground, either in brick trenches or a composition prepared for the purpose, and of course the services could be attached so as to supply the whole of the intervening property. The area embraced by the proposed installation was shown on this plan (producing plan), and it was rather curious that it exactly accorded, as Mr. Shoolbred had pointed out in a letter to him, with the powers obtained in the first Provisional Order. It was proposed that the electricity should be supplied at what was known as low pressure. That could be done within a certain radius of the station, and with electricity delivered at low pressure there was absolutely no danger to life or property from fire. As a consequence insurance companies did not charge any extra premium for insurance on buildings thus lighted. Of course a very important element in considering the probability of success in such an enterprise as was now proposed was the question of price. The committee hoped to be able to sell the electricity by measurement by meters, so that everyone who bought it would only pay for the quantity actually expended, instead of paying so much per lamp. Whether this could be done would, of course, depend very much upon whether the meters in existence were of sufficient accuracy by which to sell the illuminant. It had been stated that there was no meter sufficiently accurate for this purpose, but it appeared that there were six or seven sufficiently accurate to buy by. In a letter in one of the papers that day it was stated that there were at least six types of meter which were all accurate. He hoped the committee would find this to be true, for the result would be to remove from their shoulders a great amount of work, trouble, and anxiety. A unit of electricity was supposed to be equal to 100 cubic feet of gas, and by the Provisional Order a maximum charge was allowed of 7d. per unit, which would be equal to 5s. 10d. for 1,000 cubic feet of gas. The committee thought that 5d. would probably be the charge which they would have to make, which would be equal to 4s. 2d. for 1,000 cubic feet of gas, or a little less than double the present price of gas in Bradford. Many people in the town had said that if the price of electricity was only double the cost of gas they would be glad to adopt it. Mr. Priestman proceeded to say that the works which it was proposed to erect would be built in a permanent and substantial manner, and would form part of a comprehensive and complete plan, which could be fully carried out if found desirable. The committee had entered into no undertaking whatever with regard to dynamos, engines, or anything else; nor were they at all wedded to any particular plan. He had no doubt the discussion that day would result in offers of land not yet put in the market, and possibly the committee might get even a better and more central situation than that which he had named. They came before the Council, therefore, merely to ask that they might be allowed to go on in the best way they could to provide an installation of the kind which he had mentioned. He had no doubt that the Council would pass the resolution. If they did, the first duty of the Gas Supply Committee would be to appoint a subcommittee to visit London and Leamington for the purpose of seeing the installations there. At Leamington there was an installation, not yet, he believed, quite completed, similar to that which the committee were now proposing to establish in Bradford. Alderman Priestman went on to say that the Gas Supply Committee did not feel very anxious to prove that electricity was an article very superior to gas, because they had such a very large stake in their gas plant, but he thought that the Council might pass the resolution with confidence, and that the installation would be worth all it cost if only used to light the Town Hall, the Markets, and the Free Library. The Council had an example in the chamber that day of the effect of gas on the atmosphere, and there were many complaints of inefficient ventilation in the Town Hall. Some money had already been spent in experimenting in ventilation, and he believed it was in contemplation to spend well on to £1,000 more. If gas in the Town Hall were replaced with electric light, and the consumption of the oxygen of the air thus obviated, the building would, he thought, be found to be as well ventilated as the Council would care for. As to the Free Library, there were complaints—and all who had libraries or pictures would readily understand it—of the damaging effects of the products of the combustion of gas upon them, and he had been told by the chairman of the Free Library Committee that that committee would hail with great satisfaction the introduction of electric light. The uses to which electricity could be put were, of course, of a varied character, and not confined to lighting, and he need only mention, as a probable result of providing the installation, the introduction of additional trades into the town, such as electroplating, &c. Applications had already been made by electroplaters to come into Bradford and establish their trade there. This would, of course, be a great advantage to the town, and there was every prospect of these anticipations being realised. Where a small motive power was required he had no doubt that the electricity would be extensively used, and it was not unlikely that all the tramcars would before very long be driven by small electric engines, if the companies could obtain the power from such a source as the committee intended to provide. In conclusion, Alderman Priestman expressed the hope that he had said enough to induce the Council to comply with the very modest request of the committee, and the belief that they would have no cause to regret their action if they did so.

After a very few remarks from other members of the Council the resolution was unanimously adopted without further comment.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 9th inst. amounted to £4,756.

EASTERN TELEGRAPH COMPANY.—This company announced the payment on the 14th January next (incorrectly given in our last issue as the 4th January next) of interest at the rate of 3s. per share on the preference shares of the company, less income-tax, for the quarter ending 31st December, 1887; and on the same day an interim dividend will be paid of 2s. 6d. per share in respect of profits for the quarter ended 30th September, 1887, on the ordinary shares of the company, free of income-tax. The company's register of transfers will be closed from the 6th to the 13th January, both days inclusive.

ELECTRO METAL-EXTRACTING COMPANY.—The prospectus is issued of the Extended Electro Metal-Extracting, Refining and Plating Company (Limited), the capital of which is £150,000, in £1 shares, of which 40,000 will be issued as fully-paid, in part payment for the existing patents, plant, machinery, and lease of works. The company is formed to acquire and work the business and patented electro processes for the United Kingdom of the Electro Metal-Extracting, Refining, and Plating Company (Limited), for refining, separating, and recovering tin, copper, and other metals and alloys from scrap and old metals, dross, slags, and mining tailings, and for electro-galvanising iron goods. The patents were drawn and examined by Messrs. Carpmael and Co., the patent agents, and the processes have, it is stated, been thoroughly tested and proved by actual operations during the past twelve months at the works which have been established in Hutchings-street, Millwall, while the results are such as to show beyond doubt their great value. According to the prospectus, the works have a wharf frontage to the River Thames of about 270ft., with a gridiron in the river capable of accommodating vessels up to 1,000 tons, which produces a revenue, and being near to the East and West India and Millwall Docks they possess unusual facilities for both importing and exporting goods. The lease of these premises, the machinery, and the plant are included in the purchase, so that the company are in a position to commence business immediately on completion of purchase. The prospectus states that the revenue from the London works when completed may be estimated as follows:—Profit on creating 100 tons of tin scrap per week, £277, or per annum £13,850; profit on galvanising 50 tons of iron goods per week £75, or per annum £3,750; profit on refining 50 tons of copper (exclusive of the gold and silver recovered) per week £250, or per annum £12,500; total profit £30.100. The company propose to erect and carry on four such works, in addition to the London works, and it is intended to erect them in Swansea, Birmingham, Liverpool, and Glasgow, the centres of the manufacturing districts, where the materials for the company's operations can be obtained, and the products disposed of to the greatest advantage.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 9th were £3,878, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

The Phosphor Bronze Company write us as follows:—It may interest your readers to know that the price of our "Vulcan Antifriction Alloy" remains unaltered, notwithstanding the great advance in price of tin, which enhances in proportion the cost of genuine Babbitt's metal.

Messrs. Bayley Brothers, of the Selborne Works, Walsall, inform us that finding their electrical business steadily increasing, they have decided to appoint Messrs. Montague J. Scott and Co., of 100, Jermyn-street, London, as their London representatives.

Messrs. Hull and Stewart, after being employed as engineers by Messrs. Woodhouse and Rawson for many years, have gone into partnership as electric light engineers and contractors, with offices at Newark-on-Trent.

NEW COMPANIES REGISTERED.

THE PORTLAND ELECTRIC LIGHT COMPANY (LIMITED).—Registered by Robinson and Turnbull, 4, Mitre-court-chambers, E.C., with a capital of £45,000, in 9,000 shares of £5 each. Object: To enter into contracts for electric lighting with any corporation or person, and to supply all machinery, motors, generators, lamps, materials, or appliances in connection with the business of the company.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 501.—Vol. XX. FRIDAY, DECEMBER 23, 1887. Price 4d.

NOTES.

An output of 25 watts per lb. of dead weight is by far the best performance for a dynamo—in this particular—that we, at present, remember to have come across. This, however, is the figure claimed by Messrs. Paris and Scott for a small machine running at 1,000 revolutions, of which some particulars will be found at the end of an article further on. Of course, we shall not be at all surprised if the above remark leads to our being further instructed in this matter—a result which we should hail with satisfaction.

It would, for instance, be interesting to know how the turbo-dynamos of Messrs. Clarke, Chapman, Parsons and Co. compare in this respect, the weight of the dynamo alone being taken into consideration.

We happen to remember that some months ago a certain electrical engineer (a man, by-the-bye, of no slight eminence in his profession), confided to us that he was sometimes animated by a secret desire to build constant potential dynamos with cast-iron field-magnets, "and would, in fact, have done so long ago but for the look of the thing." So, now that the example has been set elsewhere, we shall expect ere long to learn that our esteemed friend and excellent neighbour has at length found the courage of his convictions.

Cast-iron magnets for incandescent dynamos having recently been successfully introduced, it only remains for some one else to build a machine—as we believe Mr. Kapp once threatened to do—with a single horseshoe magnet turned upside turned down, with its pole-pieces bolted to the cast-iron bed-plate. Magnetism is cheap. This reflection should afford some consolation to the makers of dynamos when copper is dear.

If this should meet the eye of Mr. B. E. Sunny, of Chicago, we would invite him to consider the meaning of the word "banter." In America, as in England, it may be sometimes called chaff; but with us it can rarely be mistaken for a sneer. We have never sneered at Mr. Sunny, and, what is of more consequence, never at "American achievements." The editor of the *Western Electrician*, where Mr. Sunny accuses us of these offences, confesses that the facts as presented at the time in Mr. Sunny's paper on underground wires were liable to be misunderstood. This was precisely our opinion; and in commenting on the paper we playfully pointed out where the misunderstanding would come in. That we were not able to export at the same time the requisite sense of humour for understanding us is to be regretted; but it is an explosive commodity that will not bear transmission through the post.

Our readers will scarcely fail to be struck with the extreme beauty and ingenuity of the electrometer fault-resistance test employed by Mr. Arthur Wright at Brighton, and which is described in another column. The electrometer designed for the purpose is also wonderfully simple and accurate, and, like all his special apparatus, was made by Mr. Wright himself.

Next to the unique and successful character of the operations carried on at Brighton, perhaps the most striking point is the simplicity and effectiveness of the means employed. For instance, the "empirical loop test," or, as it might be called for the sake of the alliteration, the "lineman's loop test," is almost comically simple in application. It is evident that, notwithstanding the admirable work already done (in particular by Mr. Kempe), we have not yet exhausted either the requirements or the possibilities of the situation in adapting refined methods of testing to the work of heavy electrical engineering.

We shall next week give some information as to the cost of supplying electricity at Brighton, particularly with regard to the relative distribution of the various charges which go to make up the total. The figures will be found to be of a very instructive character, and, so far as they can be generalised from, they tend perhaps to upset some of the ideas most commonly held in this country as to central station lighting.

We quote the *Brighton Herald*:—"For the first time in its history, strange and eventful though it has been, the Royal Pavilion at Brighton was the scene on Thursday of a brilliant entertainment in honour of one of the native Princes of India. The event might justify a disquisition more or less to the purpose respecting the chain of historical circumstances that has led to so unique an incident, for, to compare small things with great"—but hold! it may be this article is copyright; let us therefore judiciously skip a column or so. And now, good friends, read this:—

"The entertainment was, in short, complete in every respect, even down to the presence of a staff of detectives and of Police Firemen (under Mr. T. Gibbs), who, *as the electric light was used* in all the principal rooms, were held to be necessary."

Digitized by Google

Our contemporary omits, perhaps, to mention that, the town water having recently been laid on, a staff of the Royal Humane Society were present (under Mr. T. Noodle), in case the water-pipes should burst.

ACCORDING to a writer in the *Boston* (U.S.) *Herald*, the telegraphs in Mexico afford abundant exercise and recreation to the monkeys which abound in the wooded districts of that country. As many as a hundred able-bodied members of the tribe may often be seen looped together, swinging in festoons from the wires, or performing acrobatic feats, which frequently end in bringing the gymnasium to earth, and utterly breaking down the telegraphs. Here would be a chance for Mr. Caws and his spring shackles.

THE new electrical type-writing instrument invented by Mr. Higgins (of the Exchange Telegraph Company) is one of the most beautiful (if superlatives are permissible in a technical journal we might almost be inclined to say *the* most beautiful) and certainly one of the most ingenious adaptations of electrical and mechanical science which has ever come under our notice. The first set of apparatus of this description has quite recently been completed, and the engraving in the text was taken from this instrument, which Mr. Higgins has been good enough to send for our inspection. The mechanical action (when actuating the armatures by hand) appears to be quite perfect in every particular, and although we have not as yet had an opportunity of testing its performance when driven by a battery, the result is not open to further question. The most remarkable part of the design lies in its entire freedom from intricate and delicate mechanism; the whole of the moving parts are readily accessible, and the adjustments are of a simple and obvious character. The convenience of an instrument of this description, which prints on letter paper like an ordinary type writer, will be fully appreciated.

Is it possible that the manufacture of electric bells and accessories, of however "improved" a type, can find profitable employment for a capital of £100,000? Considering the number of manufacturers already in the field we take leave to doubt it. Can a series of patents for electric bells and accessories be worth £30,000, one-half in cash down? We doubt this still more.

A CORRESPONDENT, signing himself "A Poor Victim," writes to us from Newcastle complaining that he has been done out of three guineas by a medical electrician, who sold him an electropathic belt which proved to have not a trace of electricity in it; and he asks us to expose the imposture. We should like to oblige our informant, and still better to warn the public generally against this species of quackery. But in the first place we are not sure that the belt was any the worse for not being electrical, or that it would have been any the better for being what it professed to be. An "electric belt" has, perhaps, a trifle better *raison d'être* than a "magnetic" belt. But in the present state of electro-medical science it is at least certain that the indiscriminate use of such appliances can do little or no good and probably little harm save to the pockets of too credulous victims. When a "cure" is effected by such means we take it that the elements of success consist (in various proportions) of fortuity, faith, and flannel. The second of these is doubtless often a potent factor, while the third is perhaps the most trustworthy. Our correspondent has our sympathy, but a blind reliance in advertising quackery is scarcely calculated to win our esteem.

Telephones in the United States.—The number of telephones in use in the United States is at present estimated at 175,000.

Midhurst (Sussex).—The "Lighting Inspectors" of Midhurst, Sussex, are open to receive tenders for lighting the streets of that town "by oil, gas, or otherwise."

French Cables in the West Indies.—A cable is about to be laid for the Société Française des Télégraphes Sous-Marins, connecting Cuba with Venezuela, Curaçoa, St. Domingo and Hayti.

Ramsgate.—We understand that Mr. R. Coveney, of Ramsgate, is preparing plans for a central lighting station in the town, a large number of customers having been already secured.

Train Lighting in Russia.—The South-Eastern Company of Russia have adopted the electric light on their trains, not only in the carriages, but the usual engine lanterns are replaced by two powerful arc lamps.

Boiler Explosion.—On Friday last a boiler explosion at Westchester, near Philadelphia, destroyed the electric light plant, and left the town in darkness. Six persons were killed and six injured by the explosion.

Exeter.—Preparations for the introduction of the Thomson-Houston system are being actively pursued in Exeter. The fixing of the poles and wires in High-street, Queen-street, and a portion of St. Sidwell's is nearly completed.

Lighting of Corn Mills at Bacup.—In reference to the Note on this matter in our issue of December 9th, Mr. H. Bury, of Manchester, who carried out the work, asks us to correct the name, which was erroneously given as Mr. W. Bury.

Lamp Factory.—We learn from a French contemporary that Messrs. Woodhouse and Rawson are about to build an incandescent lamp factory at St. Nicholas d'Airlemont, in the Department of Seine-Inférieure. It is said that the whole of the staff will be of French nationality.

Leeds.—At a joint meeting of the Leeds Corporation Electric Lighting and Fine Art Gallery Committees on Monday the question of the lighting of the new art gallery was considered, and it was ultimately decided to employ incandescent lamps for lighting the whole building.

Glasgow.—The Bazaar Committee of the Glasgow Town Council has agreed to recommend the acceptance of the tender of Mr. Richard Miller, 54, St. Enoch-square, for the electric lighting of the Corporation Bazaar and City Hall, amounting to £1,448. 7s. 6d. The Thomson-Houston system will be employed.

Cheltenham.—The local journals of this town have lately contained a discussion on the *pros* and *cons* of the question of introducing electric street lighting. So far the *cons* appear to have it; but for a wealthy and fashionable town like Cheltenham, doubtless the introduction of both arc and incandescent light is only a question of time.

Digitized by Google

Telephonic Communication between Paris and Lille.—There are now five long-distance telephone lines from Paris, the latest addition being a line to Lille, which was opened for use a few days since. The other four lines run to Havre, Rouen, Rheims, and Brussels. The users of these lines are instructed to speak "slowly, distinctly, and in a high-pitched voice."

Installation Work.—Messrs. Woodhouse and Rawson have recently carried out the following installations :—At Messrs. Crosse and Blackwell's ; Messrs. J. J. Murphy and Co., Cork ; at Lord Brassey's residence, Park-lane, the museum containing curiosities collected by the late Lady Brassey ; also a temporary installation for the Alpine Club at Willis's Rooms.

Improvement in Continental Telegraph Service. — The *Diario Popular*, of Lisbon, states that the international telegraph service over the land lines has lately shown a very great improvement both in clearness and rapidity, messages from Versailles having been received in Lisbon with a delay of fifteen minutes only. The improvement is attributed to the use of the Hughes apparatus.

"Scientific News."—We are informed that *Scientific News for General Readers*, which has hitherto been published monthly, will, owing to its increasing popularity, be published weekly from the first week in January next. This journal "seeks to explain in untechnical language useful and interesting applications of science, and to make its readers acquainted with the scientific events and discoveries of the day."

Trade Catalogue.—We have received a copy of the third edition of the illustrated price list and catalogue of electric lighting apparatus and material issued by the Electrical Apparatus Company, of 4, Charing-cross. The pamphlet contains a very complete list of electric light apparatus and fittings of all kinds ; some of the electroliers and coloured glass shades are of particularly handsome and effective design.

The "Dynametroscope."—A contemporary journal, *Invention*, contains an account of a new instrument called a "dynametroscope," by means of which we learn that "with a given electromotive force and current the candle-power of any dynamo may be read off, and the laborious calculations hitherto necessary for the attainment of such results entirely avoided." The construction of the apparatus is not explained.

The Atlantic Cables.—The *Central News* says :—"The cable between Germany and Valentia, by which a portion of the Continental traffic for America is sent to the United States *viâ* the Anglo-American lines, has been interrupted during the past few days. It is believed the cable has parted somewhere off Hastings. A special staff has been sent from the Telegraph Construction and Maintenance Works to repair the fault if possible.

"A Little Parable."—A correspondent writes us as follows : "It appears to me that the Fire Risks Committee of the S. T. E. is like unto a certain fox, which was called Brer, of whom it is written 'Brer Fox, he lay low and said nuffin, all winter ; an when May come Brer Fox he find sayin nuffin berry hard work, so he done take holiday till next winter. Den Brer Fox he lay low again an kep on sayin nuffin' (till *next* May ?)."

"Electrical Plant."—We are pleased to note the continued success of the monthly trade catalogue published by Messrs. Wheatley Kirk, Price and Goulty. In addition to the advertisements of new and second-hand plant some editorial matter has recently been introduced which will tend to increase the value of the publication. The publishers write to us to the effect that subsequent issues will appear on the 1st instead of on the 15th of the month, as heretofore.

Submarine Illumination for the Torpedo Service.—Experiments have recently been made in the United States Navy on the employment of submarine incandescent lamps by torpedo boats. The plan adopted is to mount a 100 candle-power lamp at the end of a submerged pole 20ft. in length, which is lowered vertically from the side of the vessel. By this means the water is illuminated to a radius of 150ft., though the light is not visible from a distance.

Derry Electric Lighting Scheme.—A few days since the Derry Corporation had under consideration several contracts for the lighting of the city by electricity. After some investigation and discussion it was decided to instruct their solicitor to put before counsel the relations subsisting between the Corporation and the Gas Light Company, and have a legal opinion on the powers of the Corporation to enter into the proposed scheme. The question is causing a good deal of interest locally.

Telephones in Hospitals.—The Equitable Telephone Association have received an order to fit up eleven of their A type "Swinton" telephones in the Hospital for Consumptives, Ventnor, Isle of Wight, for the purpose of communication between the different wards, the resident doctor, the porter's lodge, &c. The instruments will be connected to a central exchange, so that they can all be switched into communication one with another. It is expected that this installation will, when completed, save the hospital authorities much time and trouble.

Telephonic Communication with Ships at Anchor.—It is stated that the Compagnie Transatlantique, whose vessels sail from Havre, are about to establish telephonic communication with their ships while lying at anchor in the roadstead by means of a cable attached to the buoy to which they are moored. Considering the difficulties encountered by the Telegraph Construction and Maintenance Company and the enormous expense incurred in maintaining communication between the shore and the lightship of Walton-on-the-Naze, we are rather inclined to doubt whether this will be found a practicable scheme, even in a sheltered roadstead.

The Royal Institution.—The following are the lecture arrangements at this Institution up to Easter, 1888 :—Sir Robert S. Ball, six lectures (adapted to a juvenile auditory), on "Astronomy : The Sun, Moon, Planets, Comets, and Stars," commencing on the 27th inst. ; Mr. G. J. Romanes, 10 lectures, "Before and After Darwin ;" Mr. Hubert Herkomer, three lectures, on "The Walker School," "My Visits to America," and "Art Education ;" Mr. C. Hubert H. Parry, four lectures, on "Early Secular Choral Music ;" the Rev. W. H. Dallinger, three lectures, on Microscopical Work, with Recent Lenses on the Least and Simplest Forms of Life ;" Lord Rayleigh, seven lectures, on "Experimental Optics ;" and Mr. William Archer, on "The Modern Drama : French, Scandinavian, and English."

Telephone Communication between Brighton, Lewes, and Shoreham.—The South of England Telephone Company announce that they have established telephone exchanges in Lewes and Shoreham, and that they are now in direct communication with the Brighton exchange system. The use of the trunk lines for inter-town communication is free of extra charge to subscribers, from their own instruments only. Public call rooms are established from which communication with any of the towns connected may be held on payment of sixpence. Up to the present ten public call rooms have been established, of which there are six in Brighton, three in Lewes, and one in Shoreham. Trunk line connections are also in

Digitized by Google

process of erection with Eastbourne and Worthing, and the company hope early in the ensuing year (1888) to announce their completion.

The Paris Exhibition, 1889.—The Commission of Control and Finance of the 1889 Exhibition have decided that the Exhibition should be open in the evening, and lighted with the electric light. The entrance fee in the evening will be two francs, of which one franc is to be paid to the electric light companies that will illuminate the buildings and grounds. These companies will continue to receive half the entrance money paid in the evening till the total thus received amounts to two million francs, after which the State will share in the profits. This arrangement, which was adopted by seventeen votes against eight, was hotly opposed by M. Christophle, in the name of the Society of Guarantee; and on the proposal of M. Dautresme, Minister of Commerce and Industry, it was decided that a special commission should investigate the contracts to be made with the various electric lighting companies.

The Gime Carbons.—In all cases where a strong green tint is not objected to in an arc light, it appears that carbons manufactured by a new process due to M. Gimé possess great advantages. Not only are they consumed much less rapidly, but we learn that with carbons of equal size, and with the same current, nearly three times as much light is produced by the Gimé carbons as by the ordinary forms. For this reason they are about to be tried by the French Government for lighthouse purposes. The green tint is due to the presence of boron. The process of manufacture is as follows:—A very pure form of coke is reduced to a fine powder and mixed with a hydro-carbon (*houille-maigre*). To this is added a saturated solution of boric acid at a temperature of 50deg. C. The plastic mass thus obtained is moulded under pressure, and raised to a red heat in a furnace. The processes are thus very simple, and the carbons are said to be made at a very economical rate.

Use of the Telephone on Railways.—Far more extensive use is made of the telephone on the railways of the Continent than in this country. In Germany in particular an extensive series of trials have been carried out with this instrument on the State lines, and the Government has just issued a memorandum to the railway companies embodying the results of their experience. From this it appears that for local and branch lines, where the traffic is small, the telephone has in many cases entirely displaced the telegraph; and of late it has been considered safe to extend the system to busier lines where the telegraph was at one time considered indispensable. In these instances, however, we take it that the example of Germany is not at all likely to be followed in this country. But for intercommunication amongst the different departments of the larger stations the telephone is in almost universal use, and it is stated that no insuperable difficulty is experienced owing to the induction from other wires. All long-distance trains also carry telephone apparatus to be attached to the telegraph wire in the event of a breakdown *en route*. This is an example which it certainly might be useful to imitate.

The Electric Lighting of the City.—On Tuesday last a meeting of the City Commission of Sewers was held at Guildhall, Mr. Graham King presiding. A report was brought up by Mr. J. C. Bell from the Streets Committee submitting for adoption a proposed arrangement with the Anglo-American-Brush Electric Light Corporation for lighting a district of the City. It stated that the area proposed to be lighted was that comprised between the Royal Exchange, Poultry, Cheapside, St. Paul's-churchyard, Ludgate-hill, and Fleet-street, on the north, and Queen Victoria-street and the Thames Embankment on the south. The arrangement contemplated the furnishing of 169 arc lamps of 2,000 candle power at a cost of £26 per annum each, in place of 616 gas lamps, or in the narrow parts glow-lamps or arc lamps of less capacity and greater number might be substituted at an additional cost of 50 and 25 per cent. respectively. The contract would be for a term of seven years certain, with power to renew for a further term of seven years, provided the Commission did not grant to other companies powers with regard to private lighting. At the instance of Mr. Parnell, the consideration of the report was adjourned.

Transmission of Power in Madrid.—The Madrid paper *El Economista* gives some particulars of a movement now under discussion in the Spanish capital for the formation of a joint stock company for the purpose of supplying electric light and motive power by power derived from the River Manzanaras. It is proposed to divert 2,000 litres of water per second from the river, so as obtain an effective force of 2,700 horse-power. Conveying this force by electricity, and converting it into mechanical motion, it is estimated that the available power will be reduced to one half, namely 1·350 horse-power. It is proposed to supply power for ten hours daily, and to accumulate the supply of water at the rate mentioned above during the fourteen hours when the machinery would not be working. The *Economista* enters into a calculation to show the financial success awaiting such a scheme should it be carried out, and sums up by stating that the advantages which would accrue to the industries of Madrid would be unquestionable. Instead of paying 50 centimos de peseta (about 5d.) per hour, which it states is the cost per horse-power of gas engines, the user of the new power would only have to pay 25 centimos, say, 2½d. per hour; while, in the case of lighting, taking the cost of gas at 5 centimos per light per hour, the electric light of equal brilliancy would cost 2½ centimos only.

An Automatic Potential Recorder.—We learn from *Industries* that "Herr Zacharias, of Berlin, has introduced an apparatus for automatically recording the pressure in the mains of an electrical supply system which is in use here with very satisfactory results. The apparatus, which has been made by Messrs. Siemens and Halske, consists of an ordinary clock with a pendulum making eighty beats per minute, and which closes every forty-five seconds an electric contact, throwing an electro-magnet into circuit. The armature of this magnet is balanced by a spring, so as to occupy a definite position when the standard pressure of 120 volts is in the mains. If the pressure is either greater or smaller the armature occupies positions to either side of the normal. The armature is provided with a pin, in front of which slowly revolves a cylinder carrying a paper strip, with a line marking the position which corresponds to 120 volts. At the moment of making contact with the electro-magnet the current is also sent through another electro-magnet, which presses the cylinder for an instant against the pin on the armature of the first magnet, and thus a hole is pricked, and the position of it on either side of the 120-volt line shows the variation of pressure existing at the moment. After a few seconds the current is again interrupted, and the same cycle of operation is repeated every forty-five seconds; thus a series of marks is obtained on the paper strip, forming a record. Herr Zacharias also tried to obtain an absolutely constant record by keeping the paper strip always up to the pin; but this not proving successful, the plan of recording at short intervals was adopted."

Dublin.—At a recent meeting of the Dublin Town Council a resolution to proceed with the scheme for lighting a certain

Digitized by Google

portion of the town with arc lamps was brought up and confirmed. It was incidentally mentioned that the amount of the highest tender received was in very close accordance with the estimate of the city engineer, but the sum was not named. In reference to the early history of electric lighting in Dublin Mr. Councillor Mayne told the following pathetic story:—The reason why money was lost in connection with the Electric Lighting Company in Dublin was that they were not only the first *bonâ fide* commercial electric lighting company started in the three kingdoms, but he believed they were the only one. They had to learn all their business and had to work with the only class of engine—the semi-portable one—which was at the disposal of the electric lighting companies at that date. They had consequently to spend more upon coal for the working of their concerns by nearly ten times as they would have had if they had the improved engines. Even with all that disadvantage they had just turned the corner, and they had succeeded in making just as much profit in winter as compensated for any want of profit in the summer, and they had just arrived at a stage when the use of a little more capital spent on additional plant would have enabled them to earn so much profit that they could have given their shareholders a dividend. But just then the electric lighting panic set in, and their shareholders, forgetting that they were shareholders in a *bonâ fide* commercial concern, put themselves in the same boat with the shareholders of bogus companies, who were losing, and deserved to lose, the investments they had made The shareholders got nervous, and in obedience to their fears the company was wound up. No sooner was the company out of existence than the gas company bought the plant cheaply and charged considerably more than the electric lighting company were charging, and making a profit out of it. He would be very much surprised if the corporation, with the advantages they had, were not able to light the city very much better, and at a less cost than the gas company did.—The resolution was carried.

The Lighting of Weston-super-Mare.—At the last meeting of the Weston-super-Mare Town Commissioners the Lighting Committee, of which Mr. Heap is chairman, presented an interim report as to their action with regard to the lighting of the town after the present contract with the gas company expires. On November 14th they directed the clerk to ask the gas company a series of questions in reference to the terms upon which they would supply the Board with their commodity at the termination of existing arrangements, and to specify what would be their prices for illuminating the town with gas to the present extent, to an increased extent so far as regarded the esplanade, or with the exception altogether of the Sea Front, &c. The committee met again on the 24th ult., and were joined by Mr. Massingham, managing director of the Taunton Electric Lighting Company, who informed them that the greater number of electric lights used the less per light would be the charge; that sixty lights would be a good number to have, as they would just employ two dynamos; that each light would give 1,200 candle-power; that the lights should be placed 100 yards apart; that should sixty lights be used for six hours per night they would cost £18 per light per annum; that Taunton was paying at the rate of £22. 10s. per light per annum; and that on sixty lights being adopted they would entail, according to his (Mr. Massingham's) estimate, 1d. in the £ extra on the general district rate for the year. The committee, accompanied by Mr. Massingham, then proceeded to the Sea Front and other parts of the town to view and select sites for lamps in the event of the electric light being adopted and the plant fixed. Twenty-three sites they apportioned the Sea Front, and the remainder they distributed over the principal thoroughfares of the town. Again on the 28th ult., and again on December 5th, the committee met, and decided that, in case the electric light were adopted, sixty lights would be required for the illumination of the town. They also determined to advertise for information and tenders in regard to the provision of the electric illuminant, determining as the latest time at which tenders should be sent in the 19th of the present month. On the 12th inst. the committee had the replies of the gas company to hand, but regretted to ascertain that their question in respect of the gas lighting of the town apart from the Sea Front had not been answered. They instructed the clerk to make further inquries of the company, and to elicit the company's terms for long contracts. They were now awaiting a further communication from the gas company.

Indian Government Telegraph Department.—By the recent reorganisation of the Indian Government Telegraph Department the grades and emoluments of the higher or gazetted appointments have been very materially improved, and the service now stands second to none in respect of position, pay, and pension. In consequence, however, of the block in the service, which it is the object of the new rules to remove, the service staff is complete, and only two appointments to the grade of assistant-superintendent are at present made every alternate year, candidates being prepared at and passing through the Royal Indian College of Engineering, Cooper's Hill, Staines. The staff now sanctioned is as follows:—One director general, Rs.3,000 per mensem; one deputy director general, Rs.2,000 per mensem; two directors (construction and traffic), Rs.1,600 per mensem. The superintendents will be divided into three grades—four first grade, on Rs.1,125, rising to Rs.1,500; nine second grade, Rs.1,000 to Rs.1,500; sixteen third grade, Rs.850. *Assistant superintendents* will be divided into two classes of two grades each, twenty in first grade (first class) on Rs.700, and twenty in second grade on Rs.550; sixteen in first grade (second class) on Rs.400, and sixteen in second grade on Rs.300. The *strength* of the *superior establishment* will ultimately be fixed at eighty-four. *Personal allowances* will be given on the following scale for meritorious service:—Assistant superintendents, first class, first grade, Rs.100 after 22 years' service, and second grade Rs.100 after 17 years; first grade, second class, Rs.100 after 12 years, and second grade Rs.50 after 7 years. Officiating promotions will in future be from class to class, not from grade to grade. The following new pension rules for the superior establishments are sanctioned:—All officers who have served 18 years, of which not less than 16 have been on active service, are eligible for retirement. Pensions will be granted on the following scale to those whose resignations may be accepted:—(*a*) The pension which would be due, under the existing rules, of officers concerned retired on medical certificate; (*b*) Additional pension calculated on the following scale: to officers under 50 years of age, Rs.1,000 per annum; officers in their 51st year, Rs.900; officers in their 52nd year, Rs.800; officers in their 53rd year, Rs.500, provided such resignations are submitted before March, 1888. Officers who have completed their 53rd year will receive no extra pension, but may retire under the provisions of clause (*a*). Similarly, all officers who attain 16 years' active service on any date subsequent to October, 1887, are eligible to retire on the above terms, provided their resignations are received by the Government within six months of the day on which they attain the necessary qualification.

SOME ENGLISH CENTRAL LIGHTING STATIONS.

I.—BRIGHTON.

(Continued from page 128.)

The Mains.

The total length of the mains is at present about fifteen miles, the farthest point reached being about three miles distant from the station. The conductors are carried overhead, and consist of No. 7 B.W.G. bare copper wire. So carefully have they been erected, that up to the present time the company *has never had a broken span*. The total average loss by energy absorbed in the mains amounts to 5 per cent. This is known by comparison of the number of volt-hours paid for by the consumers, with the number registered by the meters which are connected with the terminals of the circuit. It has been determined in all further extensions of the system to employ fluid insulators (Johnson and Phillips), and a considerable number have already been put in.

Insulation Resistance of Mains.

A test for insulation is taken twice every day on each circuit. Practical experience proves the absolute necessity of this precaution when employing a high-tension system. It is, moreover, very necessary to be able to distinguish between a general leakage more or less equally distributed over the whole system, the amount of which is of course largely dependent on atmospheric conditions, and (on the other hand) a fair degree of insulation on the whole accompanied by a fault, or incipient fault, of comparatively low resistance. For instance, an insulation resistance on a wet night of 10,000ω per mile if equally distributed, though lower than desirable, is not found to be a dangerously low figure; but an insulation resistance showing a resultant fault of the same value, but which meant megohms on the greater part of the line and a 10,000ω resistance at one particular spot, would be a highly dangerous condition.

Empirical Loop Test for Position of Fault.

When the current is *not* on, the determination of the position of a fault presents no difficulty. The position and average

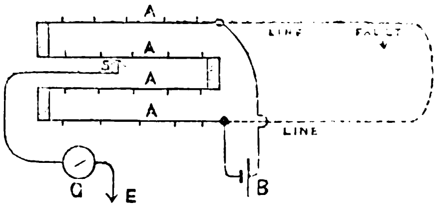

Fig. 11.

value of the resultant fault when the line is in proper condition is carefully recorded from time to time, and this value is so high that if any serious leakage occurs at any other point on the line it practically cancels the normal resultant fault, so that an ordinary loop test will indicate the position of the new fault with a degree of accuracy which as a rule leads to the speedy detection of the exact spot. The method of applying the test has been reduced to so simple a form that the ordinary lineman can carry it out. This simplicity is attained by the graduation of the slide-wire bridge in terms of the corresponding lengths of the line itself. This will be easily understood from the diagram, Fig. 11. A A A A represent four lengths of German silver wire, connected by copper strips at alternate ends, and mounted vertically upon a screen. Close at hand is a mirror galvanometer, G, the terminal of which is connected to earth, and the other to a slider, S, which makes contact with the German silver wire. A battery, B, is joined up across the terminals of the slide resistance wire, and the line to be tested is connected as a shunt to the battery, so that we have the conditions of the ordinary loop test. The empirical graduation of the scale is effected for each line separately when first installed or altered. For this purpose a lineman is sent round the circuit who makes dead earth at each installation successively. When earth is made at the first house a balance is obtained on the bridge, and an arbitrary reference number is marked upon the corresponding position of the scale. This number is entered in a book opposite the name and address of the consumer in question. The lineman then proceeds to the next house and so on. It may be mentioned that communication is maintained between the lineman and the station through a telephone which is temporarily connected with the line. When a new installation is put in its "bridge number" is taken in the same way. For the actual test it is therefore only necessary to obtain a balance, and then on referring to the list the lineman is at once directed to the spot where the fault will probably be found.

Before applying this test it is, however, necessary to ascertain that there are no lamps in circuit, otherwise the results would obviously be inaccurate. For this purpose it is only necessary to take the "copper" resistance of the line. This is usually done with a differential galvanometer, and as the true resistance of the line itself is known it is not needful to measure the actual resistance of the circuit, but only to see whether or not a balance is obtained with the normal adjustment.

Insulation Resistance (*continued*).

After some experience Mr. Wright came to the conclusion that the measured value of the insulation resistance while the line was not in use gave very little idea of the true insulation resistance with a P. D. of 2,000 volts at the terminals of the circuit. It was sometimes found that the insulation tested very high with the battery, but yet gave manifest signs of imperfection under the E.M.F. of the machine. It therefore became necessary to devise means for measuring the actual resistance of a fault (or the resultant fault), and to do this while the current was on. For this purpose Mr. Wright devised an extremely ingenious electrometer test which we will now describe. We may premise that a special and very practicable form of electrometer is employed, which we shall describe later.

Electrometer Test for Resistance of Fault While Current is On.

The method of carrying out this test is as follows:—(1) The positive pole of the dynamo which is supplying the circuit to be tested is connected to one terminal of the electrometer

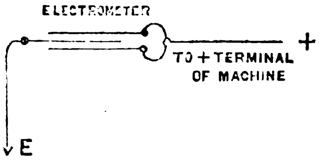

Fig. 12.

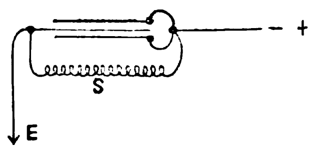

Fig. 13.

(there are no "quadrants" in the instrument employed), and the other terminal is connected to earth. The deflection obtained is proportional to the fall in volts from the positive pole up to the fault*—call this p. The connections are shown in Fig. 12. (2) The positive pole of the machine is next connected to earth through a high resistance shunt s, and the P. D. between this pole and earth is again measured, which is, of course, less than before. Call this q. Then if x be the resistance of the fault it can be shown that

$$x = s\,\frac{p-q}{q}.$$

The connections are shown in Fig. 13.

The proof is as follows:—

In Fig. 14 let A B represent the resistance of the line, A being connected with the + and B with the − terminal of the dynamo:

* In order to make this point perfectly clear it may be as well to point out that in the theory of the test it is assumed that the resistance of the remaining resultant fault is very great in comparison with that of the fault which is being tested for. This is also the usual condition of practice. But the resultant and the actual fault may be considered to stand in series connection in the earth circuit. Hence the current through the fault during the first part of the test is negligible, and the electrometer may be considered to be joined up directly to the conductor at the point in question.

Digitized by Google

and let A E be the difference of potential at the terminals. Then the slope of potential is represented by E B. Let there be a fault at F, then the fall of potential up to the fault is represented by E K; call this p.

Now let the + pole be connected to earth through a shunt, s, whose resistance is represented by K L, thus forming a new circuit, whose resistance is made up of that of the line up to F, the fault itself, and the wire s, which is usually about 100,000ω. The resistance of the line is, of course, negligible in this combination. Let x be the resistance of the fault. Then the slope of potential in this circuit is represented by the line E M N.

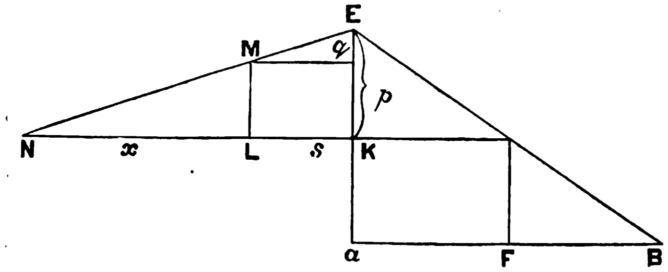

Fig. 14.

The electrometer being connected as before, a reduced deflection is now obtained which represents the fall of potential over the shunt s, and is therefore equal to E H, or q. But the current in the shunt is the same as that through the fault resistance x, and we have therefore, by similar triangles,

$$\frac{p}{x+s}=\frac{q}{s},$$

$$\text{or } x=s\frac{p-q}{q}. \qquad \text{Q.E.D.}$$

A still more simple proof may be obtained alegebraically; but the physical conditions of the test are not so clearly brought out. The algebraical proof is obtained at once by writing

$$\frac{p}{q}=\frac{x}{\frac{xs}{x+s}},$$

from which $x=\frac{s\,(p-q)}{q}$ as before.

THE BRIGHTON ELECTROMETER.

Mr. Wright's electrometer (Fig. 15) is a gravity instrument; it is excessively simple in construction, and well adapted for

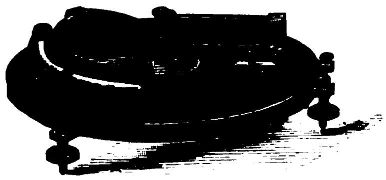

Fig. 15.

use under the practical conditions of an electric lighting station. Its reliability has been fully demonstrated by the excellent service it has rendered at Brighton. It consists of two curved plates of metal, somewhat of the shape of the longitudinal section of a kidney bean, set one over the other with a suitable space between, and inclined to each other in such a way that they are nearest together at the narrower ends. The two plates being fixed in this relative position are then slightly tilted from the horizontal, so that the narrower ends are raised a little higher from the ebonite base. Between the plates, which are in metallic connection, is placed a movable tongue or armature supported on an axis, which is slightly inclined to the horizontal in such a way that when the needle is deflected it retains its central position between the inclined plates in all positions. The tongue carries a pointer which moves over a scale on the front of the instrument, and it has also a projecting arm carrying a small weight. The zero mark on the scale is towards the lower and more widely separated ends of the plates; the needle is balanced in this position, but, owing to the tilt, when the needle moves into any other position the weight is raised against the force of gravity.

The action will now be easily understood.

The points whose P.D. is to be measured are connected one to the needle and the other to the metallic plates. The static charge then tends to deflect the needle against the force of gravity, as just explained. By means of careful experiment Mr. Wright has succeeded in adjusting the shape and position of the various parts so as to obtain a proportionate scale. There is evidently a wide field for an instrument of this class, which is, of course, as well adapted for alternating as for continuous currents.

(To be continued.)

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY A. E. KENNELLY.

CHAPTER IV.—*Resistance (continued).*

(Continued from page 130.)

39. Since the resistances which are dealt with in telegraphy may sometimes be exceedingly small—perhaps that, for instance, of a short length of thick copper wire offering a minute fraction of an ohm—and on the other hand may be very great, such as that of the insulating gutta percha covering of a short length of cable core amounting, it may be, to billions of ohms, it is convenient to adopt two secondary units, one a multiple and the other a sub-multiple of the ohm. Thus a million ohms is spoken of as a megohm, and is usually represented for brevity by the last capital letter, omega, of the Greek alphabet (Ω)—thus 227·5Ω means 227,500,000 ohms. The ohm itself is commonly represented by the small letter omega (ω). One-millionth of an ohm is called a microhm, and has at present no representative symbol. Thus, 7,560 microhms is the same as 0·00756ω.

40. Resistances that are connected in series or simple circuit are always directly additive. This is obvious from the fact that any resistance may be regarded as an equivalent length of some particular wire, and we have seen that the resistance of a wire is proportional to its length. Thus, if a circuit be composed of a battery of 40ω total internal resistance, an overhead conducting wire of 50ω, and the copper wire wound on the coils of a sounder of 35ω, then we may regard that circuit as being equivalent to 135 miles of wire whose resistance is 1 ohm per mile, the resistance of forty such miles being in the battery, fifty in the line, and thirty-five in the receiving sounder.

41. Resistances that are not connected in series, but side by side, or as it is termed "*in multiple arc,*" cannot of course be additive, for between the points they connect there is more than one path, and the conductivity is increased by each additional path so introduced. We therefore have in this case the conductivities additive. Suppose A B C and A D C to be two wires connected at A and C, and each offering 5ω, then the conductivities of these wires are each $\frac{1}{5}$ or 0·2 mho. The double conductor may be regarded as a single conductor of double sectional area, so that we know its conductivity will be doubled, that is 0·4 mho, and the resistance of the two together, or, as it is termed, their *joint resistance*, will be $\frac{1}{\cdot 4}$ or 2·5ω, half that of either branch. So that the joint resistance of two equal wires is half that of one, of three equal wires one-third that of one, of ten one-tenth, and so on. When, however, the wires are not equal the case, though not so simple, is similar. Thus if in Fig. 13 A B C

Digitized by Google

had 10ω, while A D C had 20ω, then the conductivity of A B C would be $\frac{1}{10}$ or 0·1 mho, that of A D C $\frac{1}{20}$ or 0·05 mho. The joint conductivity is their sum, 0·1 + 0·05, or 0·15 mho—that is, $\frac{1}{0·15}$, or 6·667ω, and similarly with any number of parallel conductors. For example, in Fig. 14 five resistances are shown in multiple arc, of 150ω, 60ω, 55ω, 2,000ω, and 80ω respectively; their conductivities will therefore be $\frac{1}{150}$, $\frac{1}{60}$, $\frac{1}{55}$, $\frac{1}{2000}$, $\frac{1}{80}$ mhos respectively—that is 0·006667, 0·016667, 0·018182, 0·000500 and 0·012500 mhos. The joint

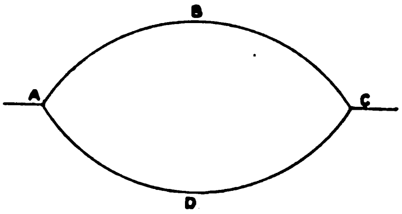

Fig. 13.

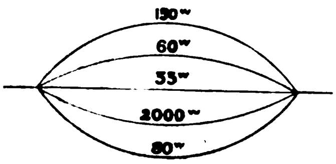

Fig. 14.

conductivity will be the sum of all these, namely, 0·054516 mhos, and the joint resistance will be $\frac{1}{0·054516}$, or 18·343ω.

Chapter V.

Current.

42. Having examined the nature of electromotive force as supplied by batteries, and of resistance, we are now in a position to deal with the laws which relate to the current which flows in any given circuit, laws which are among the simplest yet most important considerations of the subject.

43. Reverting to our typical form of simple cell at Fig. 1, page 31, we saw that no current flowed in the circuit B E F G H if the wire F G H were severed at any point. When a circuit is interrupted at any point it is said to be *opened* or *broken*, and when re-established to be *completed* or *closed*. Every possible circuit, even though it may embrace, as in telegraphy, hundreds of miles of conductor, and the earth itself between that conductor's terminals, may be regarded as a simple extension of that wire F G H, and hence a current in a circuit ceases and recommences upon the complete opening and closing of that circuit at any point, even though in the battery itself, as, for example, by withdrawing and replacing a battery plate in its cell.

44. Fig. 15 represents the simplest form of telegraphic circuit. A, B, and C are supposed to be three stations connected by the overhead conductors A B and B C. At each station there is a key, K, a sounder, S, and a switch, *s*. At A there is a battery, B, one pole of which goes to the key and the other is connected to the earth, say by a large metal plate buried in the ground. A similar earth connection is made at C. The switches have each two positions when turned to the right, as at B they break connection between the key terminals; and when turned to the left they re-establish it by making contact at *c*. The keys remain up while at rest through the action of a spring. If, now, all the switches are turned to the left or closed, a complete circuit is formed from the battery through s_1 S_1 A B, s_2 S_2 B C, s_3 S_3 and the earth, and a current will therefore flow through all the three sounders. The action of the current on the sounder we shall not at present consider, but it will suffice to observe that when the current passes through the wire of its coils, those coils attract the soft iron cross-piece or *armature* on the beam above, and pull it down against the attraction of the spiral spring *p*. If, now, B opens his switch by turning it to the right the circuit is completely interrupted at his key, the current ceases, the spiral springs reassert their control over the armatures, which rise to their upper limiting stops. If, now, B depresses his key for a single moment and releases it again, he will have closed the circuit during that moment at the key contact, the current will have passed during that interval, and caused the armatures of all three sounders to be attracted down to their lower stops, only to recoil again when the key K_2 rises; so that whatever contacts B makes, whether long or short, at his key, will be faithfully reproduced on all three sounders, whose armature levers follow, in fact, all the up and down motions of B's key. When B has finished sending he closes his switch, and either A or C can open their switches and reply to him in the same way. Thus, with one battery, E, any convenient number of stations can communicate with each other along a line of conductor by inserting a key, switch and sounder. This system is called the closed-circuit system, already alluded to in paragraph 16. It is in almost universal use in the United States, but is not so suitable for the conditions of European telegraphy, and is scarcely employed at all in England, one great disadvantage being the waste of battery power while the circuit is silent, as the current is normally always flowing.

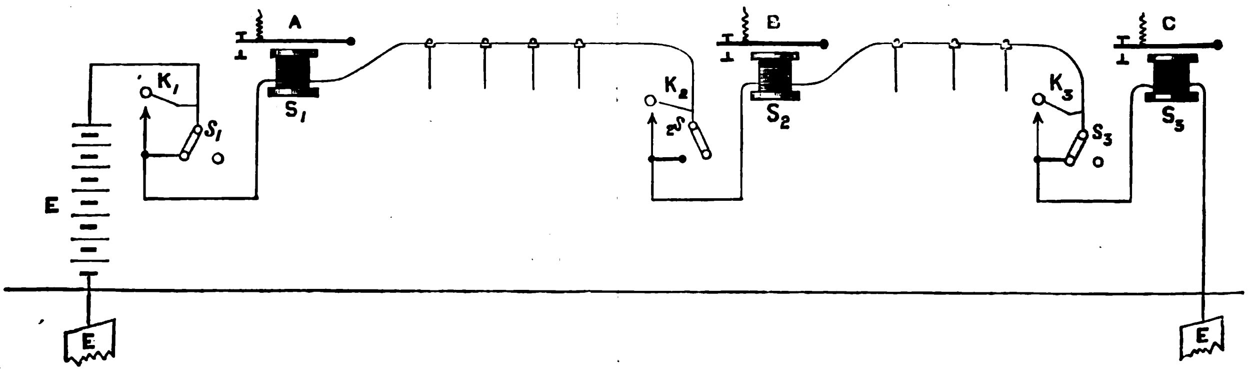

Fig. 15.

45. The instant such a circuit as that in Fig. 14 is closed a current commences to flow, but it does not instantaneously arrive at its full ultimate strength. A certain amount of time is required for the current to rise to its constant maximum limit, and this period of time is called the *variable period* of the current's flow. The duration of the variable period depends not only upon the nature of the circuit itself,

Digitized by Google

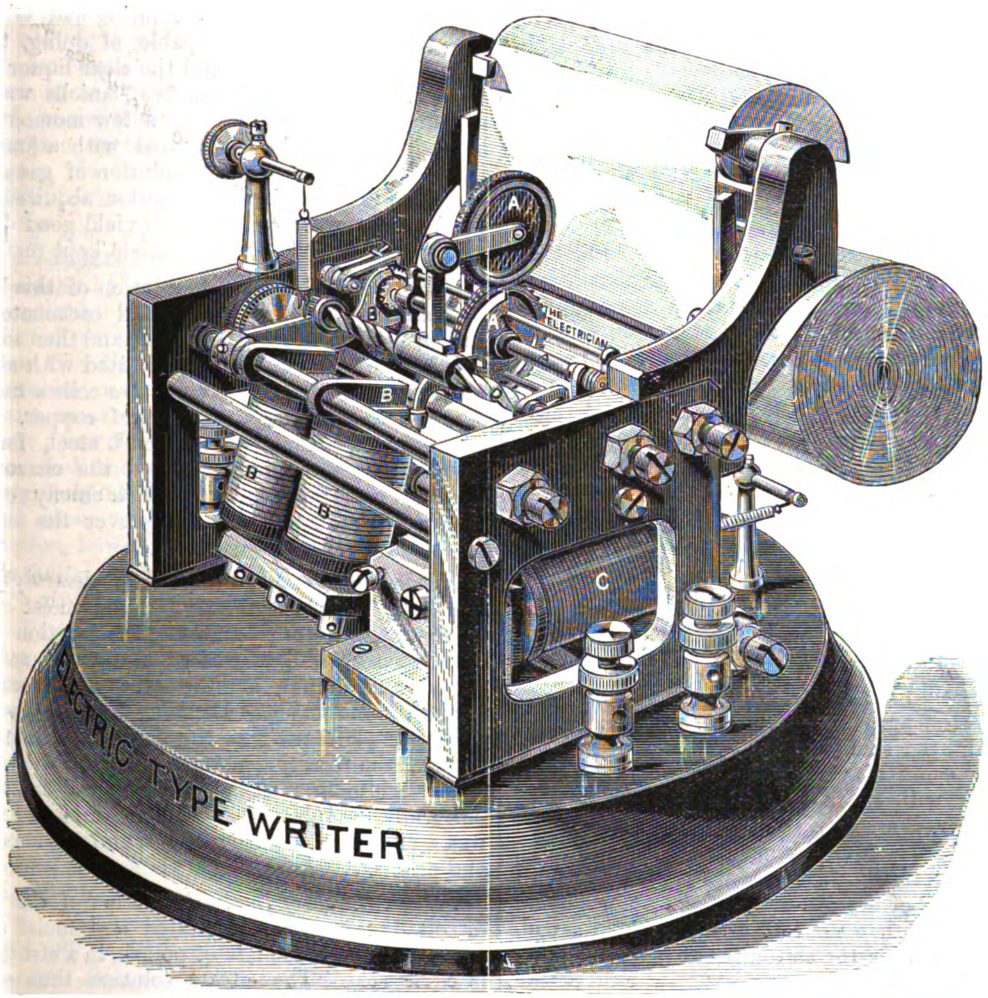
but also upon the nature of the space surrounding it; other things being equal, however, it increases with the length of the conductor. Practically, however, the variable period is in the case of overhead land lines exceedingly short. For example, with an ordinary No. 8 overhead wire 100 miles in length, with a battery and earth at one end and earth at the other—that is to say, with no telegraph instruments—the current at the end distant from the battery would arrive at 99 per cent. of its ultimate maximum value in 0·0021 second, or about $\frac{1}{500}$th part of a second, so that although the duration of the variable period is increased by the introduction of receiving apparatus into the circuit, still that period is with overhead lines so short that it may be neglected, except on lines worked at a very high signalling speed.

(To be continued.)

AN ELECTRICAL TYPE WRITER.

BY MR. F HIGGINS.

This apparatus, which fulfils the functions of a type writer at any distance from the keyboard, consists of a type wheel, which contains the letters of the alphabet, numerals, and stops. The rotation of the type wheel is effected by means of intermittent currents transmitted from a commutator under the control of a pianoforte keyboard acting on propelment pallets carried by the lever suspended over an electro-magnet. The number of currents transmitted determines the position of the type wheel with respect to the swinging frame, which serves as a guide to the paper and at the same time as a platen to make the impression. This frame is pivoted at its end, and carries an armature which is acted upon by an electro-magnet.



A A A Type Wheel Axle and Ink Loller. B B B Type Propelling Pallett and Armature Magnet.
C Printing Magnet. D Screw fcr Returning Type to Zero.

The type wheel is automatically traversed horizontally after the printing of each letter, in order to take up a position for the succeeding character until the end of the line is reached, when the operator restores the type wheel to the starting position by pressing the appropriate key. At the time this takes place the paper is advanced sufficiently to space between the lines, and the operator may by making successive contacts rapidly advance the paper as much as may be required either to commence a fresh subject or to eject sufficient paper to bring the end of the message well into view.

The lateral spacing of the characters is uniform, and is determined by the printing operation. The platen frame in falling back rotates a screw which carries the type wheel and ink roller. The spacing between the lines and the return of the type wheel to the starting point are effected at the same time by pressing a key which corresponds to a position on the commutator and the type wheel which is not occupied by a letter. A pin projecting from the type axis at this point causes the intervention of a block which acts as a fulcrum to a lever connected to and worked by the platen, but which only

Digitized by Google

comes into operation to release the type wheel when thus provided with a fulcrum, and consequently only when the act of printing takes place with the type wheel in this position. A spring returns the type wheel to zero.

Synchronising between the receiving and transmitting apparatus is secured by means of a lever, which is geared to a type axis by friction, and is carried by the revolution of the latter into the path of a projecting pin. Upon a print being made this lever is reset at its starting point, but should three revolutions of the type wheel be made without a print the wheel will be arrested at zero. By commencing a message always upon the zero or spacing key of the transmitter the apparatus will be in unison.

Ink is supplied from an inking wheel in the usual manner.

INCANDESCENT LAMP MANUFACTURE.—AMYLOID CARBONS.

BY NELSON K. CHERRILL.

Mr. Swinburne says in his article No. III. (*Electrician*, Vol. XVIII., p. 122) that it is very difficult to get the production of amyloid constant in quality during manufacture, and I fully agree with him. But besides the causes of variation to which he refers there are, I think, others of perhaps more importance because less obvious at the moment.

Of course, in manufacturing on a large scale the supply of cotton would be derived constantly from the same source, and consequently one might be led to imagine that the product, so far as the cotton itself was concerned, would be very constant in its quality. But there are some considerations which would seem to show that this is not altogether the case. If we take the cottons of several different makers we shall find on trial very appreciable differences in the time of immersion necessary for proper conversion, or in the strength of acid necessary for conversion in the same time. I have met with one sample of cotton which remained unaffected by the acid even after a very prolonged immersion. Now, wherein do the differences between each sample from different makers mainly lie? I think it is chiefly in the cleaning or bleaching to which the cotton has been subject in the course of its manufacture. If the cottons of several makers be thrown together there will be found many differences of whiteness between them, and from this I gather that bleaching is carried on to a greater or less extent. Now if the varied amount of bleaching used by various makers produces a marked difference in the process, would not variations in quality (for electrical purposes) be produced by variations in the bleach action in the same manufacture?

There is another cause of variation which may be even more important. It will be found referred to in a very interesting book by Mr. Bowman on the "Structure of Cotton Fibre," published in 1881. Mr. Bowman describes, p. 55 *et. seq.*, "cotton oil" and "cotton wax," and from what he says I gather that the cell walls of the cotton fibre are impregnated with a kind of oil which, when the cotton is new, is in a condition of oil, but which, when the cotton is old, hardens more into the condition of a wax. Spinners say "new crop cotton has more nature is it." The quantity of this oil or wax also appears to depend on the ripeness of the cotton when gathered.

Now, I think, it is easy to see that the presence of such a substance as this in the cell walls of the cotton fibre may be an important factor in the final result; and especially as it is represented as undergoing a gradual change, as the cotton is kept, it may not unlikely be a fertile source of those variations in quality to which carbons made by the thread-immersing process are without doubt subject.

In 1850 a Mr. Mercer brought out a process, called after him "mercerising," by which cotton fabrics were steeped in a solution of caustic soda of 1·3 to 1·4 sp. gr., after which the fabrics are said to become much fuller and stronger. Mr. Bowman, in treating of this process, does not account for the action, but one would imagine that it had some very definite connection with the removal of the oil or wax above referred to. The writer tried a good many experiments in the direction of using "mercerised" thread for the production of carbons, and although these experiments were not extended to any large scale, there is good reason to think that carbons of much greater uniformity can be produced by preliminary chemical treatment directed against the cotton, oil or wax.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(Continued from page 136.)

Double Carbonate of Sesquioxide of Iron and Soda.—In this experiment it was desired to ascertain what kind of a deposit would be obtained from an alkaline solution. To form the electrolyte, a strong solution of bicarbonate of soda was first prepared, into which freshly precipitated carbonate of iron was gradually introduced, and the mixture well stirred. When it was found that the soda solution had taken up as much of the iron salt as it was capable of doing, the vessel was set aside for an hour or so, and the clear liquor then decanted off for use. The current from five Daniells was employed, and a copper cathode as before. In a few moments after immersion the copper plate became coated with a fine white deposit of iron. There was a brisk evolution of gas at both electrodes, and after a short time the solution acquired a brownish tint; the bath, however, continued to yield good deposits of iron for a considerable time, and the anode kept remarkably clean.

Sodio-Citrate of Iron.—A solution of this salt was prepared by dissolving recently precipitated carbonate of iron in a hot and strong solution of citric acid, and then adding carbonate of soda. The solution was next diluted with about two parts of water. With the current from five cells a metallic deposit was obtained at once upon a strip of copper, but this quickly assumed the colour of "blued" steel, for an instant only, however, when it again acquired the characteristic colour of metallic iron; the deposit, which chiefly occupied the lower surface of the plate, refused to cover the surface nearest the top of the fluid.

Acetates of Iron and Soda.—The electrolyte was formed by dissolving recently precipitated and moist carbonate of iron in acetic acid to saturation; the solution was then diluted with twice its bulk of water; acetate of soda was then dissolved in the liquid, and the solution was ready for use. The current from five small Daniells, in series, was employed, and a copper plate used as the cathode. Immediately after immersing the receiving plate it became coated with a bright and silvery white film of iron, the deposition taking place very uniformly, and the coating well retaining its character. There was a moderate evolution of gas, and the anode remained clean and bright.

Potassio-Citrate of Iron.—A solution of this salt was made by dissolving recently precipitated and moist carbonate of iron, prepared with carbonate of potash, in a strong and hot solution of citric acid. The citrate solution thus obtained was then neutralised with carbonate of potash, and was then tried in its concentrated form, when the receiving plate (a strip of sheet copper) soon became coated with a metallic film of a dark green colour. The liquid was next diluted, and a fresh plate immersed, which at once received a coating of bright metal, but not of so good a colour as that obtained from the simple citrate of iron. The plate was allowed to remain stationary for a minute or two, when the dark green film again appeared upon its surface. A freshly-prepared plate was now substituted, and this was kept in brisk motion while in the bath, when a silvery white film was obtained which strongly adhered to the plate. The solution was now further diluted to see if a bright reguline deposit could be obtained upon a stationary plate. Such was not the case, however, for shortly after a layer of white metal had been deposited, the coating again became covered with a dark green film. When a newly-pre-

Digitized by Google

pared plate was immersed, and kept in rapid motion, the deposit was of a good reguline character, very white, and, as before, very strongly adherent. In working this solution it was noticed that the metallic deposit, as in some other cases, commenced at the upper portion of the cathode, gradually proceeding downwards.

Chlorides of Iron and Potassium.—Solutions of the respective salts were mixed, and electrolysed with a current from two small Daniells. Only a slight trace of metal appeared upon the upper part of the cathode, while a copious dark green salt was formed, which in a few minutes floated on the surface of the liquid to the depth of about half an inch.

Perchloride of Iron and Chloride of Potassium.—A solution of chloride of potash was added to one of perchloride of iron, and a current from two Daniells employed. A copper plate promptly became coated with a bright film of iron of good colour in this solution, the anode surface being about one-half that of the cathode. There was a brisk evolution of gas, with which the solution soon became impregnated throughout. After a short immersion the plate became spotted in parts with minute dark specks, which were easily removed by scouring with silver sand. The plate being again returned to the bath received a further coating of white metal, which appeared to be exceedingly tough, for electrolytic iron, for when a corner of the coated plate was turned down, forming a sharp bend, there was no evidence of the deposited metal having separated from the underlying surface of copper. It was noticed that the anode kept perfectly clean during the electrolysis. This result from a persalt of iron was highly satisfactory.

Magnesio-Citrate of Iron.—The electrolyte was formed by dissolving freshly precipitated carbonate of iron in a strong hot solution of citric acid and then adding hydrated carbonate of magnesia until the solution was nearly neutral. The liquid, when cold, was diluted with about twice its bulk of water. With a current from two Daniells a good deposit of iron, but of a greyish white colour, was at once obtained upon a copper plate. After a short immersion the coating become streaky and of a dark colour; two more cells were then connected, and an addition of citric acid made to the bath, when the character of the deposit was greatly improved, and it soon assumed a fairly good white colour, and adhered well to the copper surface. This solution, however, like the sodio-citrate, is inferior to the simple proto-citrate, from which much better results can be obtained.

Borate of Iron.—To prepare a solution of this salt a quantity of freshly precipitated and moist carbonate of iron was digested for some time in a nearly boiling solution of boracic acid. Although the carbonate is but sparingly soluble in this acid, the resulting solution, when diluted with about twice its bulk of water, formed an electrolyte from which a good bright deposit of iron was obtained upon both sides of a copper plate immediately after immersion. The current from five Daniells was used, and the surface of the electrodes was about equal. During the electrolysis the anode kept perfectly bright and clean, and the deposit maintained a uniformly bright surface throughout the trial. It should be mentioned that an excess of boracic acid was given to the liquid.

Sulphates of Iron and Soda.—A solution of the mixed salts was prepared by adding to a solution of sulphate of iron (one ounce of sulphate in ten ounces of water) about an equal quantity of a solution of sulphate of soda. With the current from five Daniells, and about equal electrode surface, a fine white and uniform coating of iron was obtained upon a copper plate a few seconds after immersion, and the deposition proceeded with perfect uniformity and with great rapidity, a good coating being received upon the plate in about a quarter of an hour. It seems probable that a bath prepared from these salts, with such modification of density as a larger trial might suggest, would prove a useful electrolyte for depositing iron for practical purposes. A second plate was next placed in the bath, and allowed to remain for a longer period, when, as before, a perfectly uniform deposit was obtained, while the anode still retained its brightness, and exhibited signs of having been freely acted upon. On examining the solution (which was faintly acid) after the trial there was no evidence of oxidation on its surface. It should be mentioned that the deposit took place on both sides of the cathode, the back of the plate being fairly coated with iron a few seconds after immersion, indicating that this bath is a very good conductor. In many of the solutions of iron salts which I have electrolysed during these experiments, the front of the cathode—that is, the surface facing the anode—alone received a deposit of metal, while in some instances there was only a partial disposition for the metal to deposit on the back of the plate. In several instances the film positively refused to make its appearance on this surface of the negative electrode. In the present case the deposition commenced at the bottom of the plate and continued upward, which, as I have shown, is not always the case; indeed, I have known many instances in which it has been practically impossible to obtain a coating of metal upon the corners and lower edges of the cathode, even when the upper part of the plate has been coated with metal. When this peculiarity shows itself, however, it is a sure sign that the solution is an indifferent conductor.

Pyrophosphate of Iron.—A solution of this salt was prepared as follows:—A moderately strong solution of the pyrophosphate of soda was first obtained, and into this was poured, gradually, a solution of persulphate of iron. The mixture being well stirred, the resulting precipitate rapidly became dissolved, when fresh additions of the iron salt were added to nearly the point of saturation. The solution thus obtained was worked with five Daniells. In a few moments there was a moderate evolution of gas, and a dark brown salt became formed at the cathode. The plate after remaining in the bath for about five minutes was examined, when a dark blue horizontal streak of iron appeared on its upper surface, but no metal had deposited upon the remainder of the plate. On raising the anode it was found to be covered with a thick white and dense mass, which had apparently stopped the passage of the current. Beyond these effects no result could be obtained from this solution.

(To be continued.)

ELWELL-PARKER'S ELECTRIC TRAMCAR.

Messrs. Elwell-Parker have recently designed a special type of motor for tramcar work which embodies high efficiency with slow speed. A machine of this type capable of exerting 25 horse-power runs at 350 revolutions and weighs 2,000lbs. A car fitted with this motor and supplied with E.P.S. storage cells was recently tried on the Willenhall line of the Wolverhampton Tramways Company. The car has been built at Shrewsbury for Messrs. Elwell Parker (Limited), of Commercial-road, Wolverhampton, who are preparing it for the Australasian Electric Tramway Company, by whom, should it give satisfaction, it will in all probability be generally adopted.

The motor drives direct on to the axle of the car by steel chain gearing. At the trial an incline of 1 in 15 was readily surmounted. We hope shortly to give some further details of this machine.

MEETINGS OF SCIENTIFIC SOCIETIES.

(Week ending Thursday, 29th December.)

TUESDAY, December 27th.

ROYAL INSTITUTION.

3 p.m. The First of a Series of Six Lectures (adapted to a Juvenile Auditory) on Astronomy. By Sir ROBERT STAWELL BALL, LL.D., F.R.S.

THURSDAY, December 29th.

3 p.m. The Second Lecture of the above-mentioned series.

*** Particulars of meetings to be held or papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application at this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready at the end of December, 1887.

All particulars relating to Advertisements will be at once forwarded, on application.

NOW READY.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

"A POOR VICTIM."—*See our Editorial Note on this.*

THE BRADFORD CORPORATION AND THE ELECTRIC LIGHT.

The important decision arrived at by the Corporation of Bradford with regard to the electric lighting of that town furnishes material for reflections which, if not peculiarly seasonable, are at all events sufficiently agreeable and cheering to be appropriate for the Christmastide now close upon us. Bradford is not exactly the sort of place to which one's thoughts naturally wander at this season of the year; but it has the merit of being far away from the metropolis, where bustle and confusion now reign supreme for a whole fortnight, and where hardly any business of a serious kind is so much as thought of. There are some sweet spots in Yorkshire that have pleasant memories for us, and, writing as we do, with the din of London in our ears, and its fogs in our eyes, we conjure up the Christmas of old—the sunny morning, the crisp air, the frosty road, the holly-hung church and the village choir—a picture which, if it still survives, has to be sought for a good many miles away from Salisbury-court. The people of Bradford are more happily situated than we in this respect; an hour's walk in any direction will take them to scenes where an orthodox Christmas can be realised, and perhaps this will account for our attention being attracted there at this moment.

What first strikes us in reperusing the report of the Corporation meeting published in our last week's issue is the singular good fortune of the town of Bradford in having a body of men to manage its affairs whose aim appears to be to fulfil their public obligations and to provide for the welfare of the inhabitants. This, at all events, is the case if Mr. Alderman PRIESTMAN may be taken as a fair sample of the whole Council. His address on the occasion to which we refer, when the report of the Gas Committee came up for consideration, was a model of candour, fairness, and sound judgment; and showed, moreover, a quite exceptional—exceptional certainly in Town Councils—mastery of the technical features of the scheme he had to lay before the meeting. The scheme in question, as our readers are aware, contemplates providing a certain area of the borough with an installation for electric lighting, the initial cost of which is not to exceed £15,000. It is not a large undertaking, therefore; but its

Digitized by Google

past history is instructive, and the conditions under which it is to be carried out, as well as the objects intended to be accomplished by its instrumentality, are well deserving the attention of electrical engineers. It is Mr. PRIESTMAN's statement on these several heads that especially provokes our admiration.

It should be borne in mind that the Corporation of Bradford is the owner of the gasworks supplying the borough, and that to introduce a rival illuminant the most formidable of all conflicting claims—namely, self-interest—has to be overcome. That Bradford has at length satisfied itself that its gas-supplying business will not suffer, or, if it does, will be compensated for by the new business of supplying electric light, is a fact of great significance, and one which may probably lead to a similar duplication of functions in other important towns besides Bradford. Three or four years ago the Corporation of Bradford, like some other corporations possessing monopolies of gas lighting, took alarm at the sudden popularity of the electric light; and after successfully opposing the application of a London company to supply Bradford with electricity, the Corporation sought and obtained a Provisional Order under the Electric Lighting Act to supply the commodity themselves. As a matter of fact, some delay took place in acting on the powers thus obtained; and meanwhile a local company has actually effected an installation in one district of the borough, though hampered by the authority which the Corporation possess of prohibiting electric light wires over the streets. Into the merits of the dispute between the private company and the Corporation we need not enter here, further than to remind both parties that they voluntarily incurred each a certain risk—the one by invading the rights of the borough, the other by permitting its rights to be invaded. Of the two we are inclined to think the Corporation are most responsible, seeing that by condoning a private installation in the first instance they virtually confessed they had no intention of doing the work themselves. These considerations ought to, and no doubt will, assist the disputants in arriving at an amicable settlement of their present conflicting claims.

But whatever may have been the cause of this delay, the Corporation have now come to a bolder and, we must add, a more honourable resolution. Alderman PRIESTMAN reminded the Council—and it is a reminder we should like to see published very widely—that the Parliamentary powers granted to the Corporation were conditional on their being used, and were not intended merely to be employed as a shield against competition. On the contrary, every Provisional Order stipulates that if action upon it is needlessly deferred its powers may be tranferred to other persons. This point being made clear, the Council agreed with the Gas Committee that the right thing, as well as the wise thing, was to take action on their own Provisional Order. The committee recommended as a tentative experiment a small installation to be undertaken at once which could be tested during the coming spring and summer months; and, if successful, further authority would be asked to extend it later on. The plan already foreshadowed seems to be a good one so far as it goes, and if carried out under efficient supervision, and with an honest desire that it shall succeed, we have every confidence in its final, though of course gradual, adoption over a very much wider area. It is well not to start too ambitiously; and perhaps Mr. PRIESTMAN was discreet in stating that many people in the town had told him that if the price of electricity was double the present charge for gas in Bradford they would be glad to pay the higher figure for the purer article. If matters are managed properly there will be no need to tax the consumers to this extent; but at Bradford, as elsewhere, the expenditure on ventilating the public buildings ought to be taken into account, especially as the process is usually like the ventilation of our pockets at Christmas time, serving mainly to let the money out freely. The Bradford Town Hall has cost a considerable sum already in ventilating experiments, and £1,000 more was designed to go in the same direction. The electric light may save this.

Perhaps one of the most attractive features of the programme described by Mr. PRIESTMAN was the probable application of electricity to the industrial life of Bradford. He anticipated, with some show of probability, that one result of providing an electric installation would be the introduction of additional trades into the town. Applications have already reached the authorities from electro-platers to come to that place and establish their business there. Where a small motive power was required, Mr. PRIESTMAN observed, he had no doubt electricity would be extensively used; and it was not unlikely that the town tramcars would before long be driven by electricity if the companies could obtain the power from such a source as the Corporation intended to provide. This is the sort of scheme to make electricity pay, and whether undertaken by private enterprise or a public body is one which we hope to see carried out more generally during the ensuing year. The revival of trade in the closing weeks of 1887 is an encouraging sign for the country; and with improving prosperity we may confidently look forward to a rapid development of electrical industry. In this conviction our readers may depart on their holiday with easier minds, and accept our seasonable greetings, which we offer with much heartiness, in the spirit of hopefulness and courage which an old-fashioned Christmas was wont to inspire.

OBITUARY NOTICES.

PROF. BALFOUR STEWART.

It is with considerable surprise as well as profound regret that his friends and fellow-workers at Owens College, Manchester, have received the intelligence of Prof. Stewart's sudden death at his house at Drogheda, last Sunday night or early Monday morning. The professor was in Manchester on the previous Friday, and, to all appearance, enjoying his customary excellent health and spirits. He had been working specially hard, it is true, owing to the absence of his wife, who usually assisted him, and on the Tuesday he had called in a doctor for what appeared to be merely a temporary indisposition; but otherwise there was not the least cause for uneasiness, and down to the time of our going to press the actual cause of Prof. Stewart's death has not reached his friends in England.

Balfour Stewart was educated at Edinburgh University (where he graduated M.A.) with a view to a commercial career, and spent some years of his early life in Australia. His attention was soon concentrated on the phenomena of radiation and absorption of heat, and his experimental investigations in that department of physics made his name known in the scientific world. He achieved a prominent place in the early progress and development of spectrum analysis. The Royal Society acknowledged the great value of his work by electing him a Fellow in the year 1862, and by awarding him the Rumford Medal in 1868. He held for about ten years the directorship of the Kew Observatory. The greater part of his attention was now turned to the development of the subject of terrestrial magnetism, and that branch of science will be a great loser by his death. Of late years, in his capacity of secretary to a committee of the British Association, he served as a connecting link between the scientific man and the observer in all questions concerning terrestrial magnetism. While he was at Kew he established the self-registering instruments by

Digitized by Google

means of which any change in the direction and intensity of magnetic force is automatically printed. The connection between the mysterious sunspot period and terrestrial phenomena fascinated him, and he was fertile in new suggestions and valuable contributions towards a solution of these very difficult questions. In 1870 he was appointed Professor of Physics at Owens College and Director of the Physical Laboratory; and at the time of his death he was also President of the Physical Society of London, and of the Manchester Literary and Philosophical Society.

Prof. Stewart was the author of several valuable scientific text-books on Heat and Physics, and of many important papers, some in conjunction with Prof. Tait, Mr. De La Rue, and Mr. Loewy. He leaves unfinished a work on Practical Physics, two volumes of which only are completed. Of the other well-known work with which his name will be always identified, and of the religious bent of Prof. Stewart's mind, the *Manchester Examiner* speaks as follows :—

"Of deep religious conviction and a believer in Christianity, Prof. Balfour Stewart directed his active mind to some of the problems which extend farther than the solution of purely physical questions. He wrote in association with Prof. Tait a work now very widely known, entitled 'The Unseen Universe.' Few books of the day have aroused more thought or discussion, and it has been widely circulated, having passed through ten editions. In this treatise the keen scientific bent of mind which distinguished Prof. Stewart was joined to a calm investigation of supernatural phenomena. He became President of the Society for Psychical Research founded in 1882, and delivered an opening address at a general meeting of that society in June, 1884. Prof. Stewart was a member of the Church of England, and took an active interest in its concerns. He was connected with the Christian Evidence Society."

The lamented professor was in his sixtieth year.

FRANCIS C. GUILLEAUME.

In our issue of the 9th inst. we announced the death, at his residence in Cologne, of Mr. F. C. Guilleaume, the proprietor of the firm of Messrs. Felten and Guilleaume, of Mülheim-on-the-Rhine, and 101, Leadenhall-street, London, E.C., the well-known wire drawers, telegraph engineers, and manufacturers of telegraph cables, wire rope, barb wire, &c.

The deceased gentleman was born on the 30th December, 1834, and in 1865 succeeded to the sole proprietorship of the business, which, in consequence of his energetic management, has now become one of the largest, if not indeed the largest, of its kind.

Amongst the many extensive operations which Mr. F. C. Guilleaume successfully carried out may be especially mentioned the German underground system of telegraphy, which was commenced in 1876, the first cable being a length of 105 miles, from Berlin to Hallé. This proved so satisfactory that the Government subsequently decided to construct a complete network of underground telegraph cables, the total length being 3,390 miles, which for the most part were manufactured and laid by Messrs. Felten and Guilleaume.

As some recognition of the services he had rendered to industry, Mr. F. C. Guilleaume was made Chevalier of the Legion of Honour by the French Republic, by the King of Prussia he was decorated with the "Order of the Crown," and also received the title "Councillor of Commerce."

The deceased was possessed of deep penetration in commercial affairs, and the present prominent position of the firm is due solely to his restless energy and keen spirit of enterprise.

The works at Mülheim find employment for upwards of 2,500 hands, and the deceased gentleman, while being foremost in the fierce struggle in the markets of the world, did not forget the comfort and welfare of his workmen. For their benefit he invested large sums of money, and he founded for them many provident institutions, amongst which may be mentioned a fund for the support of aged workmen, for the widows of officials and foremen, and of those workpeople who are reduced through circumstances beyond their control. He also erected numerous dwellings, which are exemplary from a sanitary point of view, besides a co-operative stores and a savings bank, and we must not omit to mention the Crèche Institute for taking charge of the workpeople's infants during the day.

The funeral, which took place on the 5th inst., was an imposing sight, and at the same time a touching tribute to the memory of the deceased, not only as an acknowledgement of his abilities and achievements, but also of the interest he had always manifested for the welfare of his workmen, and thousands of people hastened to obtain a glimpse of the vast *cortége*. So large, indeed, was the procession that it took fully an hour to reach the cemetery, and besides relatives and friends the deceased was followed to his last resting place by the highest officials in both military and civil circles.

By the death of Mr. F. C. Guilleaume industry has lost one of its most ardent promoters, and his name will long be remembered as amongst those who have always had at heart the real interest of mankind.

The deceased leaves behind him a widow, three sons, and two daughters. The business will be taken over by the eldest son, Mr. Theodore Guilleaume, who has greatly assisted in the management for some years past.

SWAN'S MINING LAMP AND FIRE-DAMP INDICATOR.*

Since it has been ascertained that a very small proportion of fire-damp is sufficient to produce an explosive mixture with air heavily laden with coal dust, the old tests for the presence of fire-damp in coal mines have become entirely insufficient. Less than one per cent. of fire damp may, under certain well-known circumstances, be quite enough to originate a disastrous explosion, and hence it has become a matter of vital interest to ascertain the presence of small proportions of fire-damp in pit air. The usual means employed in testing for fire-damp is the flame of the safety lamp. The flame of a safety lamp will show by elongation when the air has become foul to the extent of 2 per cent. of fire damp, but it will show nothing at all if the proportion is less than 1 or 2 per cent., and yet 1 or 2 per cent. is quite a dangerous proportion if the air is heavily laden with coal dust, and there happens to be a long tongue of flame projected into it by a blown out shot.

I have been lately striving to supply the want of a more sensitive indicator of fire-damp, and the outcome of my effort is the apparatus before you. Before describing the apparatus I will explain the principle upon which it acts.

If we make a mixture of atmospheric air and fire-damp, and introduce into the mixture a red hot wire, combination takes place between the hydrogen of the fire-damp and the oxygen of the air, and a result of the combination is that the gaseous mixture shrinks or tends to shrink in volume. It is easy to conceive that this shrinkage, or tendency to shrink, in the volume of the gaseous mixture consequent on combustion, may be made the basis of a fire-damp indicator, for one has simply to adapt a sort of pressure-gauge to the vessel in which the combination takes place, and then the indications of the pressure-gauge correspond with the proportions of fire-damp burnt by the action of the hot wire. In the apparatus designed by me on this principle, for practical use in coal mines, in searching for gas—especially for small proportions of gas—there is a portable voltaic battery, composed of lead and oxide of lead, in dilute sulphuric acid, for the purpose of heating the wire.

This particular construction of the battery is not essential. It may be constructed (and I have sometimes so constructed it) of zinc and peroxide of lead in dilute sulphuric acid. All that is essential is a portable voltaic battery that will, without fail, make a few inches of small wire red hot, that will not be apt to go out of order, or alter much in electromotive force after being used to make a number of tests.

* Paper read before the British Association, September, 1887.

Digitized by Google

I know of no battery that fulfils all these requirements so well as the lead and oxide of lead secondary battery, constructed on the principle discovered essentially by Planté. Its electromotive force is high and comparatively constant; when the battery is properly made there is very little local action, it is easily charged, and the materials cost very little. The function of the battery is to make the combustion wire of the gas apparatus red hot.

I have added an incandescent lamp to one side of the battery in order to provide a convenient means of examining the level of the pressure gauge. The indicator is connected with the battery by means of a pair of flexible wires twisted into a cord and enclosed in an india rubber tube. These wires convey from the battery the current necessary to make the combustion wire red hot. This wire is platinum ·002 of an inch in diameter, and is wound in a spiral. The length is adjusted so that the battery will just raise the spiral to a red heat.

The spiral of platinum is, as I have said, connected by its ends with the flexible wires of the battery. There is a switch interposed (at a convenient place for the thumb to press upon) to keep the circuit broken until the moment a test is required to be made. The combustion spiral is fixed within a brass tube with a stop cock at each end. The gauge tube is of glass, and is fixed into the under side of the brass tube so that the two form a T, of which the horizontal line is the brass combination tube, and the upright line the gauge. The bores of the combination tube and the gauge tube communicate with each other, and the gauge tube is enclosed in a glass tube open at the top and closed at the bottom, and this tube contains coloured glycerine and water. The bore of the gauge tube is expanded to a bulb, which has a very minute hole at the bottom. The bulb and small hole are for the purpose of preventing the projection of the liquid out of the gauge tube, and they effectually accomplish that purpose.

There is just one other point I must mention, and that is, that the taps are made to act as switches, so that the circuit cannot be closed unless the taps are also closed.

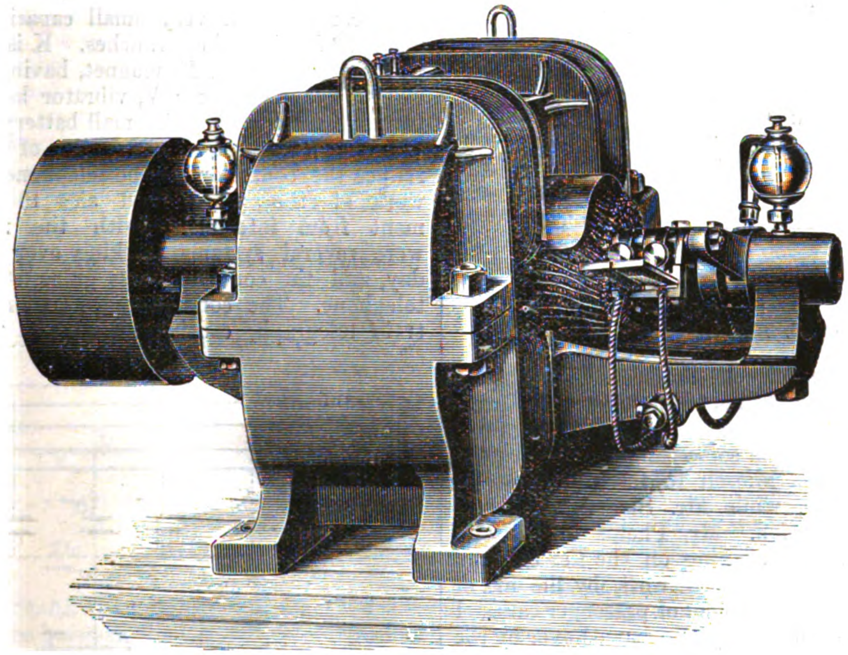
Now suppose the apparatus is taken into a coal pit, and that it is required that the air in the passages of the pit or in the workings should be tested for fire damp. All that has to be done is to pass the open combustion tube backwards and forwards a few times through the air, and then to close the taps and press the switch with the thumb during about 20 seconds, 10 seconds at a time, with a short interval between. The result of this will be that in a very short time (a few seconds if there is much fire-damp) the liquid will rise in the gauge tube above the level at which it stood at first, and the height to which it rises shows roughly the proportion of fire-damp in it.

By taking a longer time to more completely burn the fire-damp a nearly exact quantitive determination is obtained.

The degree of sensitiveness of the gauge is largely within control. By making the capacity of the combustion tube large, relatively to the calibre of the gauge tube, extreme sensitiveness is obtainable. I have found it convenient to make the bore of the gauge tube smaller for a certain distance at the lower end, and wider at the upper end. In that way I obtain both sensitiveness and range in small compass. In the tube I have here 1 per cent. of fire-damp will cause one inch rise of liquid in the gauge, and therefore it is easily readable to the $\frac{1}{8}$th of 1 per cent.

PARIS AND SCOTT'S NEW DYNAMO.

We illustrate herewith a dynamo of new type introduced by Messrs. Paris and Scott. The machine is intended to give 100 volts with 120 amperes at 850 revolutions. The field-magnets, which are of the double horseshoe type, are of cast iron, and their section is nearly three times that of the armature core. Notwithstanding this fact, and that of the moderate speed of driving, the maximum output of the machine is equal to 9·46 watts per lb. weight, the total weight being 1,268lb. The machine contains 207lb. of copper and 840lb. of magnetised iron, and measures over all 39in. in length, 30in. in width, and 21in. in height. The field is shunt-wound, and is excited with 6,292 ampere-turns on each limb. The current density in these coils is 866 amperes per square inch, and the current 2·86 amperes. The sectional area of the magnet cores is 99 square inches.



PARIS AND SCOTT'S NEW DYNAMO.

The armature is of the drum type, with Pacinotti teeth. In order to avoid the heating of the pole faces, which is apt to occur in machines of this type, owing to the non-uniform distribution of the lines of the armature field, the teeth are made very deep and narrow, and are set very close together. This not only secures a well-nigh uniform armature field, but it also prevents the disagreeable noise which toothed armatures are liable to produce. The armature measures 9in. in length, the outside diameter is 8in., and the depth of the slots 1in. The copper on the armature weighs 22lb., and is made up of 286ft. of six strands of No. 16 B.W.G. wound together,

Digitized by Google

and having a total cross-sectional area of 0·0393 square inch. The resistance is 0·029 ohm, and the current density slightly over 3,000 amperes per square inch. The iron in the armature weighs 80lb., and the total weight of the armature is 147lb. The output is equivalent to 545 watts per lb. of copper on the armature. The voltage is a little over 2 volts per yard of armature conductor. The field strength in the core, according to the figures supplied us, works out at a very high figure, namely, to 23·6 lines per square inch, allowing for the shaft one-fifteenth of the total lines. There are 168 turns on the armature, and 42 parts in the commutator. The peripheral speed is low, being only 2,200ft. per minute.

The electrical efficiency is decidedly high considering this low speed, being 94·46 per cent. In the armature at full load 417 watts are lost, and in the field 286 watts.

The mechanical construction of this armature would appear to render the machine particularly suitable for motors—especially for tramcar and electric railway work. The iron plates are made with a hexagonal hole, and threaded on a hexagonal shaft so that every plate is driven direct, and as in addition to this the conductor lies in slots, it is evident that the construction is well calculated to bear a very heavy torque. The makers inform us that great attention has been paid throughout to the mechanical details, as "they consider that durability and freedom from breakdown are of *first* importance." In this view we entirely agree with Messrs. Paris and Scott.

In cases where lightness is an important consideration, as for some classes of motors and for ship-lighting, the field-magnets are made of wrought instead of cast iron. A machine of this character, with an output one-half of that just described, namely, 6,000 watts, and running at 1,000 revolutions, with an electrical efficiency of 93 per cent., weighed only 240lb., which is equivalent to an output of no less than 25 watts per lb. of dead weight.

TELEGRAPHING TO MOVING TRAINS.*

BY C. H. RUDD.

The pioneer names connected with the system of which I write are Lucius J. Phelps and William Wiley Smith. Messrs. Edison and Gilliland have taken a leading part in making practical applications, and have secured some claims on their own account. Mr. Phelps devoted himself to the principles involved in dynamic induction, while Mr. Smith turned his attention towards static induction. Mr. Phelps used a wire laid inside of a wooden stringer running on the ties between the rails. The Smith system does good work by the aid of existing telegraph lines and the tin roofs of passenger cars. I cannot, in this article, cover all the ground passed over by the gentlemen mentioned, but will try to give a fair idea of the work of each.

I have said that Mr. Phelps placed his main line inside a wooden stringer between the rails. This wire was grounded at the ends, and worked as a closed circuit. One method of car equipment was to place an electro-magnet under the body of the car, fastening the magnet in such position that it would run at right angles to and as near the track wire as possible. A current passing in the track wire would tend to magnetise the core of the magnet on the car and produce a current in the surrounding wire. In Fig. 1 W is a sectional view of track wire; K, double point key; T, hand telephone; R, back contact relay; M, magnet running near wire W. The key open closed the circuit through the hand telephone, and was in a position to receive. The key pressed to its front stop closed the circuit through a small battery and the relay, including the back contact, producing a buzz which went into the track wire by induction. This diagram of connections is correct for the track wire when magnet M is omitted. Mr. Phelps's first idea was that he could use polarised relays and sounders in his work, but experience did not bear him out. He substituted a hand telephone for the polarised relay, and made his signals with the buzzing current mentioned. I witnessed the operation of this system on the N. Y., N. H. and H. R. R. The track is double, and the wire was laid only on one track. The signals were clear and good, but much the best when the train was running directly over the main wire, as might be expected.

The system devised by Mr. Smith is peculiarly interesting, in that it grew out of the inventor's observations upon cross talk. It is a fine illustration of the fact that natural principles may be hurtful in one field and helpful in another. In describing this system, I will refer specifically to the arrangement used at the exhibition given on Staten Island, in February, 1886. The road extended from Clifton to Tottenville, thirteen miles. The B. and O. Telegraph Company had

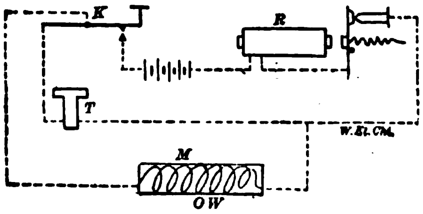


FIG. 1.

a line of thirty wires along the track. Five wires were chosen for the train telegraph. To these five wires half connections were made. Each of the branches thus formed was carried to a condenser of very small capacity. Fig. 2 shows the manner of using the branches. K is a double contact key; T, hand telephone; M, magnet, having only a primary winding of low resistance; V, vibrator kept in motion by local battery, not shown; B, small battery; C′ C″ C‴ C⁗ C′′′′′ C′′′′′′ are condensers. The action of the condensers was to reduce the confusion in the telephone caused by the regular work of the wires, and also to prevent the arrangement from interfering with the regular work. There were several systems working over the wires during the day, and the confusion was great when listened to in the telephone. The condensers discriminated in favour of the train telegraph, causing the signals to stand out alone. I

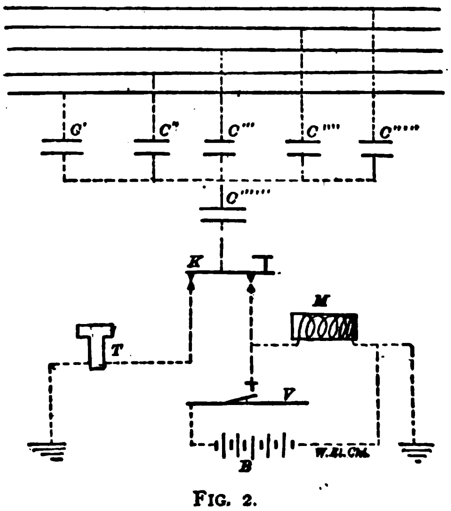

FIG. 2.

shall never forget my sensations when this style of connections proved successful. I was working upon the experiment in company with my friend S. K. Dingle, of New York. I was at the station, Mr. Dingle making the run from Clifton to Tottenville. Upon the day in question the run to Tottenville had proved very unsatisfactory. I lost communication almost immediately after the train left Clifton. It was in the middle of the day and the wires were heavy with work. I strained my ear to catch Mr. Dingle's signals, as long as the train was on the road, and then settled back in my chair to wait for the return trip. I had no particular desire for the return trip either, as I had no hope of better results. But something had to be done. Time was passing, anxious eyes were upon us, and failure was not to be thought of. We had

* From the *Western Electrician*.

Digitized by Google

used a single wire, and the idea came to me to try a combination of wires and condensers. I was aroused, for the plan seemed to have some merit. I quickly made the necessary connections, and then eagerly waited for the train to start back. When the hour arrived I was listening at my telephone, and heard what I thought was some new sort of work passing upon the wires. It was a straight buzz, unlike anything that I had heard before. I listened intently, and after a moment or two the buzz broke into Morse signals. It was "D" calling "R." I reached for my key, and did not lose communication with Mr. Dingle until the train pulled into the station at Clifton, where the tin roof on the shed cut us off. The straight buzz which I heard was "D" adjusting.

The connections used on the train were as shown in Fig. 3, in which T is the hand telephone; K, double point key; C, regular induction coil—the fine wire being represented by the wave line and the coarse wire by the straight line; V, vibrator kept in motion by magnet and local battery not shown. The key on the back stop closes circuit from roof through telephone to ground, the ground being reached through the metal work of the car under the floor. The key pressed to the front stop closes the circuit from roof through fine wire of coil C to ground. Battery B passes through the vibrator points and the coarse wire of coil C. The tone of the vibrator is reproduced in the coil, and passes to the roof when so desired for signalling. Many experiments were tried to get just the right kind of coils. We settled on the plain primary for use in the station, and a regular induction coil for the car. It seemed to be necessary to charge the roof to a higher degree than was required for the wires. I think the track exerted more influence upon the roof than upon the wires, so that the roof had to sustain a heavier tax upon its inductive energies than the wires. At any rate, it was easier to work from the station to the train than from the train to the station.

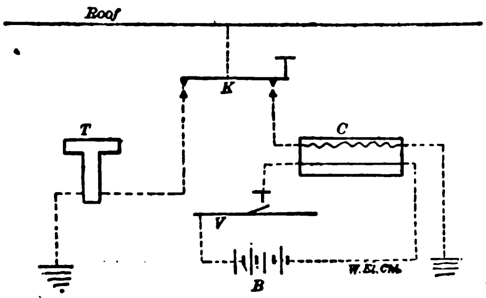

Fig. 3.

The operation of Mr. Smith's system depends upon the condenser action taking place between the tin roof, or roofs, and the neighbouring wires. With the arrangement which I have described, a charge passing to the roof is greater because of the nearness of the wires; and by just so much as this charge is greater is the strength of the train signal measured. When using the existing lines as a part of this system, it was customary to connect all the available roofs of the train together to increase inductive surface.

Late in the year 1886 some experiments were made in Western Iowa, on the C., M. and St. P. R. R. Mr. Dingle and I were still together, and had a construction train assigned to us. Instead of tin roofs we were obliged to use a flexible, insulated cord, strung on stakes set in the cars. This cord was left open at the distant end and connected to the apparatus in the caboose, just as a wire to a roof would have been connected. We did some very good work with this train. As a general thing the construction train had been working under cover of a flag or upon the best orders that could be given at the time of its departure from a telegraph station. When our arrangements were completed, we were able to follow the train wherever it might be working, and give it the advantage of any change in circumstances that favoured it, or get it out of the way of unexpected trains if necessary. In some cases we held communication over a space of one hundred and twenty-five feet between the lines and the train

At this stage of our work we came upon an unexpected enemy. One morning we began work as usual, and all went well. The train worked in a quite deep gravel pit over a hundred feet from the wires. I was in the despatcher's office and Mr. Dingle was on the train. About 10:30 a.m. I noticed a peculiar sound in the telephone, and wondered what new system of electrical work was operating in Omaha. In a little while the noise became troublesome. It would begin light and rise to a maximum, making a little explosion when it reached its highest point. These explosions would frequently cut a word out of something which the train was trying to say to me. This trouble grew worse until noon; but when the train pulled up out of the pit the margin was good enough to work over the noise. Up to noon the wires had been working smoothly. The weather was warm with a south-west wind blowing, and the sky filled with banks of fleecy clouds. I had no thought of atmospheric disturbance until shortly after noon, when the Morse relays began "clipping." The explosions in the telephone followed each other in quick succession, and work with the train ceased. Soon the switch-board began to flash fire, and the work on the wires was hard. Between two and three o'clock we had a raging storm, with severe lightning and thunder. The fact was, I had received in the telephone intimations of the storm some considerable time before the relays were in the least affected.

Time has wrought changes. I no longer telegraph through the air, but am back again into more common pursuits. Mr. Dingle still follows the fortunes of the train telegraph, and is meeting with marked success on the Lehigh Valley Road. A special wire has been built there, and placed as near as safety will permit to the top of the cars. A strong margin is thus secured, and now the system is slowly fighting its way into notice, just as each of the other electrical improvements has done.

ON THE DIMENSIONS OF THE MAGNETIC QUANTITIES IN C.-G.-S. UNITS (ELECTRO-MAGNETIC MEASURE).*

BY M. E. HOSPITALIER.

The analogy between the electric and magnetic circuits has of late been very prominently brought forward. We propose, therefore, to take a rapid survey of the several magnetic quantities, and of their expression in terms of C.-G.-S. units, so as to lay the foundation for a more exact comparison between these and the correlated electrical quantities. We shall insist more particularly upon certain new definitions, and shall show reason for the abandonment of certain expressions which lead to equations of a non-homogenous character, and are manifestly inexact.

The point of departure of the magnetic system is the law of Coulomb, which serves to define the strength of a pole.

Strength of a Pole, or Quantity of Magnetism.—The force f between two poles, m and m', at distance d is given by the expression

$$f=\frac{m\,m'}{d^2}.$$

If m and m' have each unit value we obtain—

$$m=d\sqrt{f}=L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-1}.$$

Magnetic Moment.—This is equal to the product of the strength of one of the poles by the distance between them. Calling this $\mathfrak{M}$ we have

$$\mathfrak{M}=m\,l=L^{\frac{5}{2}}\,M^{\frac{1}{2}}\,T^{-1}.$$

Intensity of Field.—When a pole, m, is placed in a magnetic field it is submitted to a force, f, proportional to the strength of the pole m, and to the intensity of the field H. We have then

$$f=m\,H,$$

whence

$$H=\frac{f}{m}=L^{-\frac{1}{2}}\,M^{\frac{1}{2}}\,T^{-1}.$$

The intensity of the field is then the *ratio* of a force to the strength of a pole.

* From *L'Electricien*, 12th November, 1887.

Digitized by Google

Magnetic Flux (number of lines of force).—If we consider a uniform field of intensity, H, and of surface, S, in a plane perpendicular to the direction of the lines of force, the *magnetic flux* which traverses the section S is the product of the intensity of the field H by the surface S. Calling Φ this flux, we have

$$\Phi = HS = L^{\frac{3}{2}} M^{\frac{1}{2}} T^{-1}.$$

It can be shown that the magnetic flux, or number of lines of force produced by an isolated pole of strength m, is equal to $4 \pi m$. We ought, therefore, to find the same dimensions for Φ as for m, which will be seen to be the case.

Intensity of Magnetisation.—By definition the intensity of magnetisation of a bar magnet is the ratio of its magnetic moment to its volume. Calling $\mathfrak{I}$ this intensity and V the volume,

$$\mathfrak{I} = \frac{m\,l}{V} = \frac{m}{S}.$$

where S is the section of the bar magnet (supposed uniform). Thus,

$$\mathfrak{I} = L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-1}.$$

This quantity has, therefore, the same dimensions as the intensity of the field.

Magnetic Susceptibility.—A bar of magnetic substance, of indefinite length, placed in a magnetic field of uniform intensity H, acquires an intensity of magnetisation $\mathfrak{I}$.

The magnetic susceptibility is the ratio of the intensity of magnetisation of the bar to the strength of the field producing that magnetisation. This is usually denoted by K, then

$$K = \frac{\mathfrak{I}}{\mathfrak{H}}.$$

Magnetic Induction or Specific Induction. — An indefinitely long bar of magnetic substance, when placed in a uniform magnetic field of strength $\mathfrak{H}$, is traversed by a magnetic flux, Φ, greater than that which traversed the same space before the introduction of the bar. The flow of force through the bar is termed the *total induction*, and the mean strength of the field within the bar is called *magnetic induction* or *specific induction*, and is denoted by the letter $\mathfrak{B}$. Specific induction is homogeneous to intensity of field.

Magnetic Permeability.—The ratio of the specific induction of an indefinitely long bar to the intensity of the field which produces this specific induction is called the *magnetic permeability*, and is denoted by the letter μ.

$$\mu = \frac{\mathfrak{B}}{\mathfrak{H}}.$$

The permeability is simply a coefficient, and has no dimensions. It is proved that the following relation exists between magnetic permeability and susceptibility

$$\mu = 1 + 4 \pi K.$$

Magnetic Potential.—The magnetic potential at a point situated at a distance l from a pole m is the ratio of the strength of this pole to the distance l.

Calling this magnetic potential $\mathfrak{V}$.

$$\mathfrak{V} = \frac{m}{l} = L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-1}.$$

The dimensions of the magnetic potential are those of a current intensity in the electro-magnetic system. This point will aid us much in understanding the magnetic circuit.

Magnetomotive Force. Magnetising Force.—A circuit through which a current is passing produces a magnetic field in the surrounding space. This field is easily defined in certain simple cases—for example, in that of an unlimited solenoid of indefinite length. If this solenoid is of uniform spiral and contains n turns of wire, then let its length be l, and let a current of strength C pass through it, the factor

$$4 \pi n C$$

is called the *magnetomotive force* of the solenoid, and the factor

$$\frac{4 \pi n C}{l}$$

its magnetising force.

It must be noticed that the magnetomotive force has the same dimensions as a magnetic potential or a strength of current $(L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-1})$, whilst the magnetising force has the same dimensions as intensity of field $(L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-1})$.

In the case of a solenoid the magnetising force is nothing else than the intensity of field within the solenoid.

The Magnetic Circuit.

We have been much led during the last few years to compare the magnetic with the electric circuit, and to find out the resemblances —by analogy—which the permanent or variable magnetic state of a magnetised medium has to the permanent or variable state of a circuit along which an electric current is passing. In certain particular cases, which we will touch on directly, the flow of force along the magnetic field is analogous to the current-strength, the magnetomotive force is the equivalent of the electromotive force, and the magnetic resistance takes the place of the electric resistance of the circuit.

In air and non-magnetic media, the analogy is perfect, and the calculations based on this analogy yield results which are in accord with those of experiment. In magnetic metals the resistance is a function not yet fully understood.

Magnetic Resistance.—Calling the magneto motive force in a magnetic circuit $\mathfrak{V}$, the flow of force produced Φ, and the magnetic resistance of the circuit $\mathfrak{R}$, the following relation is obtained:—

$$\Phi = \frac{\mathfrak{V}}{\mathfrak{R}},$$

whence

$$R = \frac{\mathfrak{V}}{\Phi} = L^{-1}.$$

The magnetic resistance in the electro-magnetic system is therefore expressed as the inverse of a length.*

Specific Magnetic Resistance.—Applying to the magnetic circuit the law of the electric circuit, we have evidently by analogy,

$$\mathfrak{R} = \rho \frac{l}{S},$$

ρ being the *specific magnetic resistance*,

whence

$$\rho = \frac{\mathfrak{R} S}{l}.$$

The specific magnetic resistance is therefore expressed as a number. It is a simple coefficient; in fact, the specific magnetic resistance ρ is the inverse of the permeability μ

$$\rho = \frac{1}{\mu}.$$

Permeability might therefore be called the specific magnetic conductivity or specific permeability.

In a recent paper "On the Theory of Dynamo Machines," Dr. Edward Hopkinson† asserts that the magnetic permeability is the inverse of the magnetic resistance. This is a mistake likely to occur in dealing with the equations of dimensions.

THE RECKENZAUN CAR IN PHILADELPHIA.

The following account of the latest type of electric tramcar designed by Mr. Reckenzaun is given in the *Philadelphia Ledger*:—

An exhibition of the new street car built for the Electric Car Company of America, and driven by electricity, was given yesterday. The new car differs in many particulars from the one with which the public are now comparatively familiar, although the principles on which it depends are the same. The source of power is electricity stored in accumulators or secondary batteries, and utilised by electric motors, which are geared to the axles. The car itself, however, is much larger than the ordinary street car and is believed to be the longest street railway car in the world. It measures overall 30ft., and its inside measurement is 22ft. It is mounted on two trucks, each having four wheels, and each truck bears an independent electric motor. Except for its size, the car does not differ in general appearance from the large cars used by the Traction Company. Its trucks, however, are constructed with steel frames, combining strength with lightness, and there are numerous other modifications. The body of the car is no higher above the wheels than the ordinary horse car, and none of the machinery is below the level of the axles except the gear wheel by which the power is applied to the axle. Under the seats of the car are arranged the storage batteries, 116 in number, and mounted on movable skids, so as to slide readily in and out of the car. On the back platform is a small square door, leading to the chamber which the charged batteries occupy, and opposite to it a hinged portion of the dasher, so that the whole collection of cells can be readily removed. When a car is to be recharged it is taken into the station and backed against a sort of double truck, arranged with wooden rollers, to receive the batteries. The door of the storage chamber being open, and the hinged portion of the dasher swung back, the exhausted battery and its supporting skid are withdrawn to one

* In the *Phil. Mag.* (May, 1883, page 310) Mr. R. H. M. Bosanquet finds that magnetic resistance is expressed as a length, and not as the reciprocal of a length. This error is produced by an incorrect definition of magnetic resistance—treating this resistance as the ratio of the magneto motive force to the magnetic induction, instead of treating it as the ratio of the magneto motive force to the flux [total number of lines of force].

† Read at the Manchester meeting of the British Association. See *The Electrician*, Sept. 9, 1887.

Digitized by Google

side of the truck. The truck is then moved sideways until the other half is in line with the car. On this is arranged a freshly charged battery which is slid into the place of the old one, and the car is ready to start on its journey. The exhausted battery is then conveyed to the dynamo on the truck, in order that it may be re-charged. Charging a car occupies a very few minutes' time, and when charged it is expected to run from four to six hours without recharging. The electric motors are situated beneath the floor of the car, one being borne on each truck.

They are of the Reckenzaun type. They are very compact, and are mounted above the axles of the wheel in line with the longitudinal axis of the car. The shaft of the motor has a worm gearing on its extremity which gears with a spur wheel on the axle of the car, which is, of course, at right angles with the motor. The Reckenzaun motor used is remarkably compact, forming an almost perfect cube about 18in. on the side, and developing nominally eight horse-power, although the inventor states it will readily work up to fifteen horse-power.

The mechanical brake on the car is new and appears to be very effective. An iron lever actuates through a series of levers a strong toggle joint, which causes two iron shoes to block the adjacent wheels of each truck.

The switch for governing the current, the alarm gong, electric light and electric signal to the switchman do not differ from those already described on the other car. Each of these devices is supplied with a shunt current from the battery and is under perfect control of the conductor or switchman.

The exhibition yesterday was very successful, the car rounding very sharp curves and surmounting grades in the yard of the company with the greatest ease, the perfect control of the movements of the car for starting, stopping quickly, and reversing being specially noticeable. It was stated that at a recent trial a single charging had been sufficient for a forty-five mile run, and that in one hour's run about the yard of the company the car had covered twelve miles. A street trip through the city was made on the old single-motor car, over the Chestnut and Walnut-street tracks. Among the passengers were Mr. Whitney, President of the Boston Consolidated Street Railways; Mr. H. H. Derr, of the Wilkesbarre and Suburban Lines; and Messrs. Widener and Elkins, of the Philadelphia Traction Company.

The Electric Car Company are now putting up large shops at Twenty-second-street and Washington-avenue, for the manufacture of electric machinery for street cars. The cars themselves will not be manufactured, but the storage batteries, motor gearing and appliances will be adapted to them. The company propose building not only the apparatus for cars driven by a storage battery, but also other forms, with overhead conductors and similar systems. It is expected that they will be fully under way by the first of the year.

THE ELECTRIC LIGHT AT THE ROCK MILL, LONDONDERRY.

[A COMMUNICATION.]

Mr. W. Shannon, of Waterloo-place, and local representative of the Gülcher Electric Light and Power Company (Limited), Battersea Foundry, London, S.W., has just completed an installation of the electric light at the Rock Mills of Mr. G. K. Gilliland, J.P.

The installation consists of a Gülcher low-tension dynamo, upwards of 80 incandescent lamps of 20 candle-power, and one arc lamp of 2,000 candle-power, which is suspended by a block and fall arrangement from a very neat pole placed in the centre of the yard of the mill. The dynamo is placed on the stone loft on a sliding bed, which is bolted to a wall about 3ft. in breadth, and is capable of running 150 incandescent lamps of 20 candle-power, and delivering 14 horse-power in electrical energy at its terminals. It runs at a speed of 860 revolutions per minute, and is driven by a steam engine which is also used for driving the machinery of the mill. The machines are surrounded by a dust-proof partition. Every safeguard has been taken against any possible chance of fire, and the installation has been put up under the Phœnix Office fire rules. There is not only a safety fuse on the main switch, but one on every subsidiary switch and on every lamp.

The lamps are suspended by silk flexible cords from ebony ceiling plates, which contain safety fuses, and are perfectly dust-proof, each pendant consisting also of a dust-proof ebony holder and a 6in. opal shade.

Lamps with flexible leads are used for placing inside some of the machines to see that the silks are working satisfactorily. The current is led from a switch-board in the dynamo room by a main cable, which supplies branch cables to each floor of the mill, offices, carpenter's shop, and stables.

In each case where the cables pass from the old to the new mill they are run in earthenware pipes lined with asbestos, which is absolutely fireproof. There is a switch to every circuit and to every two lamps.

Whatever may be the sanitary or incidental advantages of electric lighting, there is one essential condition of its adoption, viz., it must benefit the pocket of the user. The advantage comes sometimes, not merely in the bare comparison with the gas bill, but in the longer hours and better work, or reduced fire risk.

The lighting of corn mills differs somewhat from other mills; first from the crowded position of the machinery, elevators, belts, and from the inflammable nature of the machinery and of the flour itself in all its stages. We know well the explosive character of an atmosphere laden with flour dust, and the condition in all the elevators and purifiers—and, indeed, all parts of a roller mill—is such as to make an ever-present caution not merely desirable but essential in this respect. The incandescent lamp may certainly be said to provide a security from dust explosion not attainable where gas is used. A sack of flour falling downstairs opens, perhaps; the contents are scattered, and where gas is used the dust catches fire, the windows are broken, and possibly part of the building lifted. A few minutes a day is sufficient for keeping everything in order, and millowners who have power to spare in their mills will find that they will benefit themselves in every way by the adoption of this, the light of the future. The whole arrangements were carried out by Mr. A. J. Baron, of the Gülcher Electric Light Company. While on this subject we may state that Mr. Gilliland has entrusted Messrs. Victor, Coates and Co., of Belfast, with an order to erect a new engine of 200 horse-power at the mill. The engine is to be designed specially with a view to giving steadiness to the electric lights.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *Dec. 8th*, 1887.

It has been a habit, almost a settled custom, with European visitors in this country to write a book of 300 or 400 pages on it after spending perhaps a month within its borders. What these books lack in accuracy they often make up in piquancy, and that piquancy is derived not so much from the descriptive talent or keen powers of observation displayed by the writer as from the readiness with which amusing newspaper stories are seized upon and treated as if the eccentricities therein brought to light were fairly representative of the life of fifty millions of people. An incident that ought to figure in all such books is just recorded from Washington. It appears that a Congress man from one of the back districts of Texas, on arriving at Washington to perform his legislative duties this winter, proceeded to one of the leading hotels, and on going to bed carefully blew the gas out. Some time thereafter the odour of escaping gas gave warning, and the unfortunate backwoodsman was rescued by the servants. Of course, this should argue on the part of Congress men in general a sweet simplicity of manners, and it will not be surprising to see the episode related in some new book of travel as typical of social life in Washington. The story is certainly amusing, and yet it is safe to say that in many parts of Texas, perhaps even in the regions from which this unsophisticated law maker hails, the electric light has obtained a greater application even than in scores of places 25 miles from London. Thus such a city as Austin, Texas, has a plant that may safely challenge comparison with any other for completeness of detail. The station is a handsome brick building, 90ft. by 40ft., and the plant includes both arc and incandescent systems. There are 75 miles of circuits, and that the company is well abreast of the times is seen in the fact that it has already over 600 lamps in operation on the Westinghouse alternating system. Yet Austin is no exception, for as much might be said of Galveston, Dallas, Palestine, Fort Worth, Houston, and other places in the Lone Star State.

Speaking of Congress men reminds one that, though the subject of Government telegraphs promised to occupy no small share of attention at Washington this winter, there is a possibility that it may be relegated to a second or third rank in public estimation, as a vital issue, by the pronounced stand just taken in the address of President Cleveland to Congress advocating reduction of the taxes. It is shown in this address that in spite of all National Debt redemption the surplus in the Treasury next June is likely to reach £28,000,000 sterling, and obviously something must be done to lessen the burden of the people, and to release this money for legitimate circulation. While the President disclaims any distinctively Free Trade sentiments, he is careful to point out that the revenue can be reduced only by lowering the Protection tariff, and he

Digitized by Google

forces this matter on the attention of the country in a very able manner. Thus the question of Protection and Free Trade has already become a leading topic of the next Presidential campaign, and it seems likely that postal telegraphs may for a while lose their interest. It is likely that a new Tariff Bill will shortly be introduced in Congress, and that it will in various ways affect the numerous electrical industries ; but at present it is premature to speculate in that direction.

Without waiting for the action of the Government one way or the other, the new opposition telegraph company springs to its feet and salutes the great American Republic with the familiar statement that it intends to fight the great monopoly, and will never sell out. The new concern is to be known as the Postal Automatic Telegraph Company, and one of the prime movers is Mr. Chester Snow, who is already well known in such matters. It is proposed to secure for this company a charter in Massachusetts of liberal scope, and to start with a capital of £600,000, which may be increased at a later date to £4,000,000. The plan of the company, is to operate from New York to San Francisco, &c., and to put up light poles and copper wires throughout, using also new automatic systems. Should the company be in earnest—and perhaps it is not fair to believe otherwise—there is plenty of ability and material at its command for the development of its system, and there is unquestionably a very strong sentiment in favour of competition. By-and-bye, when the company has shown its hand more, it will be easy to judge how far it is deserving of sympathy and support.

The delay in the United States Supreme Court in rendering a decision on the Bell patent is giving no small amount of anxiety in various ways, but cannot be said to have affected the stability of the stock of the American Bell Telephone Company. Some of the "opposition" stocks are being boomed, and even on the most favourable consideration their prices are simply ridiculous. In all probability the rendering of a verdict adverse to Prof. Bell would bring these stocks down much nearer their actual value, whatever that may be. One of the grounds for hopefulness of those who would like to enter the telephone business untrammelled by the Bell patent is that the Supreme Court has of late evinced a tendency to limit the scope of patents and lessen the extent of the protection they may afford. On the other side, it is pointed out that even should the Bell patent be limited, or even thrown out, the Bell Company controls at least 300 or 400 other patents, has an intimate acquaintance with the business, a vast amount of capital, and a system co-extensive with the country, and that as telephone service is naturally a monopoly, in the sense that there can only be one good exchange service in each place, the company is likely to hold all that it now enjoys.

An interesting little telephonic development in Nova Scotia deserves notice. Telephonic service was recently undertaken in that province by an organisation operating the Law system. The company has made such progress that it has already succeeded in buying out the Old Bell Company there, and is to-day practically master of the situation. This has been done chiefly through the exertions of Mr. A. A. Knudson, an electrical engineer of this city, who has also succeeded in giving a stimulus to a variety of electrical applications in Nova Scotia. It is, perhaps, a little singular that this work should have been left to an American to perform, although Halifax is conveniently reached from either New York or Boston. It is understood that large quantities of electrical supplies are now being regularly forwarded to the province. American electrical manufacturers find there a good market for their productions.

The Westinghouse alternating system of electric lighting appears to be making continuous headway, and at the annual meeting of the stockholders just held at Pittsburg, it was stated that the company was earning dividends at the rate of 10 per cent. on its capital of £1,000,000. The greatest interest is being taken in all questions relating to alternating currents, and the meeting of the American Institute of Electrical Engineers held in this city on December 6th, when Mr. Wm. Stanley, jun, electrician of the Westinghouse Company, read a paper on the "Phenomena of Retardation in the Induction Coil," was probably the best and most lively of the season. Mr. Stanley presented a brief and able paper, which provoked an active discussion, lasting far beyond the usual hour.

It was mentioned last week that extensive preparations were being made to supply incandescent lighting in the upper districts of this city. Meantime work is going on actively to extend the arc lighting service, and the new East River Company, which is to operate the Thomson-Houston system, has secured an enormous seven-story building for its station near the East River and Twenty-fourth Street. It is interesting to note that in this building was temporarily placed the plant with which the experiments were made on the elevated railroad with the Sprague and the Field systems of electrical locomotion. The building has thus already an electrical history, and is likely soon to be known as the largest electric arc-light station in the world.

Electrical development in this country is attended by costly and never-ending litigation. At the present time the long list of suits pending has been added to by an action brought at Detroit, in the Brush interest, to protect the Brush arc lamp from alleged infringement by the Fort Wayne Jenney Company, and by the suit brought at Baltimore by the Consolidated Electric Light Company, controlling the Sawyer-Man patents, against the local Edison Company of Cumberland, Ma., for the infringement of incandescent lamp patents. Another movement involving litigation is that set on foot by various carbon point manufacturers, who met recently at Cleveland, and decided to sustain one of their number in a suit which the Brush Company has brought to prevent the manufacture of copper-coated carbons, in regard to which it claims exclusive rights.

CORRESPONDENCE.

THE *CONVERSAZIONE* OF THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : I am instructed by the President, Sir Charles Bright, to request the favour of your permitting him to express, through your columns, his great regret that so many of those gentlemen who favoured Lady Bright and him with their company at the reception at the Institute of Painters on Thursday evening last should have experienced so much inconvenience by the unfortunate break down of the arrangements in the cloak room.

The space available for the deposit of hats and coats is certainly very limited at the Institute, but the accommodation provided and the number of men engaged was the same as upon the occasion of Prof. Hughes' *conversazione* held at the same place last year, and as no confusion then occurred there was no reason to anticipate any last Thursday.

Mr. Hart, the resident porter and door keeper at the Institute, who had, as before, the immediate charge of the arrangements, attributes the occurrence to the circumstance that so very large a number of visitors arrived almost simultaneously at one period of the evening, that it was practically impossible for him and his assistants to deposit the coats and hats in their proper numerical order. This of course led to some delay in giving the coats and hats out, and some of the more (not unnaturally) impatient visitors then insisted on going behind the barriers to find their coats themselves. From that moment confusion reigned. I myself hastened on the scene immediately I was informed of what was occurring, and endeavoured, with only partial success, to persuade those gentlemen who had forced their way inside the barriers to retire and leave the attendants to perform their duty as well as the state of things would permit.—Yours, &c.,

F. H. WEBB, Secretary,
Society of Telegraph-Engineers and Electricians.
London, December 21st, 1887.

THE HORNSBY ENGINES AT THE AMERICAN EXHIBITION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Having seen the paragraph in your issue of November 11th, headed "Notes on the Electric Lighting of the recent American Exhibition," we beg the favour of space for a few words in reply, as several of the statements made are far from accurate.

The writer of the paragraph falls into a mistake when he says the buildings and grounds were lighted from seven 50-light dynamos and two 35-light machines driven by three of our engines, with an aggregate of 90 indicated horse-power.

Four of our engines drove the dynamos, none of which were 50-light ones, and the indicated horse-power was 348, and not 90, as stated.

The following are the particulars:—

One Engine each of

Nominal horse-power.	Type.	Indicated horse-power.	Dynamos driven.	Number of arc lights.
10	Compound	35	1	30
30	do.	69	2	61
50	do.	107	2	71
60	do.	137	2	80
		=348		

More important to us, however, is the implication running through the whole that several unsatisfactory features were shown in this installation, and that every mishap rested with us, although it is admitted that "the installation was carried out under considerable difficulties;" and yet that from the trial run until the closing of the Exhibition "the lighting was carried out in the most satisfactory manner."

It appears to us to have been the intention of the writer to unfairly praise the electricians at the expense of those who shared with them both the difficulties and the success.

For instance, reference is made to the "delay in getting the shed ready for the reception of the dynamos," but it should also be known that this shed was engine house also, so that we were even more affected than the electricians. This shed was not ready for the reception of our engines until April 27th, and we had, therefore, the short time of nine days in which to fix them; and even then the roof was not completed for three weeks after we had started running.

The shed itself was thoroughly unsuited for the purpose, and the engines might almost as well have been in the open air. They were fixed between two constantly opened doors, and the shed was so full of dust and grit as to cause the bearings, not only of the engines and shafting, but also of the dynamos to frequently run hot and need cooling.

It is, however, incorrect to say that "as many as three pumps were at work throwing water on the bearings to keep down their heating," as there was never more than one hand pump in the shed at any time.

The electricians must know that this heating was beyond either their or our control, resulting from the cause we have mentioned, as they not only put canvas round the eaves to try and keep out the dust, but also had to use ice freely almost every night on the dynamos to keep them running.

They, as well as ourselves, frequently complained to the Exhibition authorities of the state of the shed, but obtained no assistance until July, and we have seen several men attending to one dynamo whilst it was being run dead slow to cool it down.

This explanation will also account for what is described as "the general state of the engine room (which was also the dynamo room, as already stated) as regards cleanliness."

We admit that it did not "excite our admiration" or that of those in charge of the dynamos; but, we believe, all did the best they could under most unfavourable conditions.

We may also mention that the foundations supplied by the Exhibition authorities both to us and the electricians were constantly sinking.

We need only trouble you upon one other point. The only breakdown during the whole time of the Exhibition is described by your article as "caused by a tube being blown out of one of the boilers." No such thing happened at all to any of the boilers, but on one occasion (and we presume this is the occasion referred to) a plug was fused owing to our running the engine dead slow to suit the electricians, who found one of the dynamo bearings running hot. Running at such a slow speed the engine pump failed to keep up the water supply, and hence the fusing of the plug.

We need not enter into any detailed defence of our engines, which are well known as having been successfully employed in some of the largest installations, but perhaps the best answer to your correspondent's remarks is the mention of the fact that Mr. Bryson, the eminent and successful electrical engineer of the Manchester Exhibition, who has been appointed to the same office at the Glasgow Exhibition, has, after six months' experience with our engines at Manchester, pressingly invited us to send our engines to Glasgow also.

The following letter from the general manager of the Manchester Exhibition will serve to confirm his judgment, and show that where the conditions are ordinarily satisfactory, our engines do win approval and fully satisfy even those most competent to judge of their performance:—

"Manchester, 1st Dec., 1887.

"Messrs. Hornsby and Sons (Limited),
"Spittlegate Iron Works, Grantham.

"Gentlemen: In reply to your favour of the 24th ult. I have much pleasure in testifying to the admirable manner in which the driving of the dynamos throughout the whole period of the Exhibition was done by your engines.

"I have referred to the log book, and find only four trifling entries against them.

"The run has been exceedingly successful throughout, and I think I am correct in stating that we have never once, since the lights commenced, had a failure in any part of the Exhibition.

"It gives me very great pleasure to testify to this effect, and I shall always be glad to recommend your engines for similar service in future.

"I am, Gentlemen, yours faithfully,
"(Signed) Samuel Lee Bapty,
"General Manager."

With thanks for the space afforded us.—Yours, &c.,

RICHARD HORNSBY AND SONS (LIMITED).

Spittlegate Iron Works, Grantham, December 20th, 1887.

[In justice to ourselves we think it right to add that the paragraph in question reached us from an outside source, though one in no way connected with either engine or dynamo manufacture. The above letter was written in reply to a request from us that Messrs. Hornsby and Sons would correct the inaccuracies for which we had inadvertently become responsible.—ED. *E.*]

PRIMARY BATTERIES FOR HOUSE LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I must ask your indulgence in briefly replying to Mr. Ross's criticisms on mine of the 6th inst.

Mr. Ross's objection to my estimate of battery fuel cost as taken from Mr. Nursey's paper is peculiar. He prefers that I should have based it on horse-power inferred from the lamp hours rather than on the horse-power given. Mr. Ross fails to see that there are possible reasons for the apparent discrepancy he notices. Batteries of the size in question are not run to exhaustion without a gradual falling off in current, and 10 candle-power lamps are not unfrequently 5 candle-power worked to give 10 candle-power.

The figures representing the cost of fuel for battery in my table were simply taken as given. I claim no responsibility for them; they may be right or wrong; but to have based them on such unstable and uncertain ground as lamp-hours would have been inviting error.

It seems a pity that this vexed question could not have been once and for all set at rest by a public test such as has been suggested in your columns.

The other points raised in Mr. Ross's letter may be disposed of by the simple fact that any increase in the fuel costs for small engines, either by decreased efficiency of the system or

Digitized by Google

larger consumption of coal, would not materially alter the total. This will be evident on referring to the table in question, where it will be seen that the cost of fuel only ranges from 7 to 15 per cent. of that apportioned to labour. I should have had much pleasure in meeting Mr. Ross's objections on their own merits, but I do not consider myself justified in prolonging this discussion on side issues.—Yours, &c., N. G. THOMPSON.

4, Queen Victoria-street. London, E.C.,

ELECTROLYSIS OF PERSALTS OF IRON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Alexander Watt has been good enough to call attention, on page 135 of *The Electrician* of Dec. 16, to a statement of mine on page 245 of my little book on the "Art of Electro-Metallurgy," in which I say "solutions of persalts of iron yield no metallic deposit, but are reduced to protosalts by the passage of an electric current through them." He then remarks, "That this statement is not correct I will now endeavour to prove," and he proceeds to describe his experiments.

In his first article, of Nov. 11, he says :—"*Perchloride of Iron.* A solution of this salt does not yield a deposit of iron." "*Persulphate of Iron.* This salt also yields no deposit of iron by electrolysis." In his second, of Nov. 27, he commences by repeating these statements; but in the next paragraph he states that he separated iron from a solution of "pernitrate of iron" as "a thick black deposit, interspersed with bubbles of hydrogen, which rested firmly on the plate. Surrounding these gas bubbles were minute glistening particles of metallic iron, which had evidently been reduced by the hydrogen," and "the evolution of gas was much more copious with the weaker than with the stronger solutions."

In his third article of the 16th inst., after describing experiments in which he used solutions of "persalts of iron," and obtained deposits of iron upon the cathode, he concludes that he had "thus proved that iron *can* be deposited from solutions of its persalts when the proper conditions have been arrived at;" but he does not state the essential conditions.

As Mr. Watt has done me the service of criticising my statement, and has publicly asserted that it "is not correct," I beg leave to give the following evidence in support of it:—

When an electric current passes from a solution of a persalt of iron into a cathode its immediate effect is to separate hydrogen, which at first does not appear, but is absorbed in reducing the layer of particles of persalt next the cathode to protosalt by uniting with some of their oxygen or chlorine; and its next effect is to decompose the protosalt thus formed and separate its metal. So that the metallic deposit obtained by Mr. Watt was not yielded by persalt, but by protosalt. When there is but little persalt present, less of the hydrogen is absorbed and more evolved, and this agrees with Mr. Watt's observation "that the evolution of gas was much more copious with the weaker than with the stronger solutions."

Several electro-metallurgists have observed the production of protosalt, the deficiency of metallic deposit, and the waste of current in a depositing solution containing persalt of iron. Badia states (*Scientific American* Supplement, No. 478, p. 7,634) that in one of persulphate of iron "protosulphate comes from the reduction of ferric sulphate when the latter is near the cathode; that this requires an expenditure of energy, and that if we prevent contact of the persulphate with the cathode there will be no longer any reduction." "In order to obtain proof that the ferric sulphate at the cathode absorbs electric work," he made and describes a chemical experiment showing the production of ferrous sulphate; it may, however, be shown in a simpler way, viz., by change of colour of the solution.

That the persalt must be reduced to protosalt before it is further reduced to iron is proved by thermo-chemical data, *i.e.*, by the different amounts of heat required to produce reduction in the two cases; thus, whilst it requires 96,040 centigrade gramme calories to separate a molecular weight in grammes of $FeCl^3$ into Fe and Cl^3, and 82,050 to separate one of $FeCl^2$ into Fe and Cl^2, it only requires the difference between these, viz., 13,990 such calories, to reduce one such weight of $FeCl^3$ to $FeCl^2 + Cl$. It therefore only consumes about one-seventh the amount of energy to reduce the persalt to protosalt that it takes to reduce it to metal, and that is the fundamental reason why it is reduced to protosalt first.

The essential reason why Mr. Watt obtained contradictory results in different experiments was probably difference of density of current at the cathode. He has offered no proof that protosalt was not produced or present in his experiments when he obtained a deposit of iron; if he will suitably test the liquid at the cathode during electrolysis he will probably find some there.—Yours, &c., GEORGE GORE.

DR. SHETTLE'S EXPERIMENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I must ask you to be good enough to find me space in *The Electrician* for a few remarks in reply to your comments upon the paper which I read at the Physical Society on December 10.

In the first place, that paper contained no allusion to the "supposed new force" of M. Thoré.

By reference to *The Electrician* of August 19th you will perceive that my investigations were conducted with a view to show the connection between gravitation and magnetism. In my paper at the Physical Society I included the correlation of physical forces generally, and it is only in so far as M. Thoré's experiments come within the limits of these forces that my investigations have any connection with his "supposed new force."

In the second place, in spite of your kind remarks as to the way in which my experiments have been conducted, I feel compelled to point out an error in your criticisms. You say, "The whole argument can be put in a nutshell. Dr. Shettle takes a sphere of some insulating material, he winds it round with copper wire, and suspends it very delicately in front of the pole of an electro-magnet. In different experiments the winding is done in various and elaborate forms, but—and here lies the whole secret—*the ends of the wire are always joined so as to form a closed circuit.*"

If I add a few particulars as to the mode in which the wire was laid on to the spheroid mentioned in *The Electrician* of August 19th you will perceive that if there was any connection between the free ends of the strands of wire it was an accident, which, in the laying on of so many strands, could not perhaps be well prevented; but it must have been very exceptional. The large spheroid of 1,000 yards of wire, and containing upwards of 2,000 strands, was constructed with the object of testing how far currents of electricity and polar phenomena could be induced by magnetism in a spheroidal mass composed of a large number of strands of copper wire, each of which had free terminals. These terminals were all carried to four points corresponding to the terrestrial magnetic poles. These strands of wire were carried once and a half round each hemisphere and then cut off short, *care being taken not to remove the silk covering*; they were then fixed down at the proper sites with *india rubber* insulite, and as each wire stopped a little short of its predecessor, it is difficult to perceive how the free ends could have come into contact, and my belief is that they were insulated in almost if not in every case. This sphere, when properly suspended and acted upon by a magnet, behaved like an ordinary compass needle.

But I was not content with this, and commenced to reduce the thing to its greatest simplicity. I therefore made others, of which I will fully describe one. This consisted of a central sphere between two hemispheres, and was covered with three layers of wire. The first layer commenced on one side of one of the hemispheres, and after being wound closely over every portion of the surfaces terminated at a corresponding point on the other hemisphere. The spheroid was then suspended in the magnetic field, and exhibited polarity at the terminals of the wires. A second layer of wire was then wound on in the same way as the first, the terminals being ⅓rd of the circumference of the hemisphere away from the terminals of the first layer. The effect of the magnet was then again tested, and now the

Digitized by Google

pole was situated midway between the two terminals. A third layer, with its terminals ⅓rd of the circumference from each of the others rendered the polarity more confused; but motion was established at any point when the body was suspended vertically in the magnetic field.

In this case there could be no possibility of contact between the terminals of the wires, and of closed circuits being formed.

Having thus far tested the influence of the magnet upon wires with free ends, I covered wooden spheres with *insu*lated and *un*insulated copper wire, the strands being as close together as possible, and purposely converted these into closed circuits. These were tested in the magnetic field, and elicited phenomena in both cases similar to those shown by the other spheres; but the motion was greater, and especially in the case of the *un*insulated wire.

I next tested some wire helices, the strands of which were quite separate and the terminals free. These were made for me, with great exactitude in the winding and in the situation of the terminals, by Messrs. Elliott. These were wound round wooden cylinders, and when suspended exhibited rotation and polar phenomena just as the spheroids had done. Other helices of wire were made, of which the terminals were joined by passing a connecting wire through the centre of the core. When suspended in the usual way no difference could be detected in the degree of motion.

Subsequently I tested solid copper and zinc spheres, and as the phenomena exhibited tallied remarkably with those shown by the wire spheroid, I arrived at the conclusion that currents were generated in them also by the influence of the magnet, and that these currents took a definite direction from some irregularity of density in the metal.

You will thus perceive that I have tested and counter-tested the influence of the magnet upon closed circuits and upon helices with free ends, and therefore I think you will admit that my experiments are not to be explained upon the hypothesis which you have suggested. My own opinion is that these experiments show that magnetism is due in all cases to current energy.—Yours, &c., RICHD. C. SHETTLE, M.D.

[It is, we think, clear from Dr. Shettle's letter that the explanation which we offered last week does not cover the case in which the circuits were absolutely open. We hasten, therefore, to acknowledge that this experiment is of higher intrinsic value than we were inclined to suppose. At the same time we have no doubt that our first explanation is correct so far as the assumed condition is fulfilled.—ED. *E.*]

TRADE CATALOGUES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Seeing in the last issue of your contemporary, the *Electrical Review*, a note with regard to the unscrupulous piracy of trade catalogues by those wishing to profit by the work of other people's brains, we shall feel greatly obliged if you will allow us to make a few remarks, lest, as it is pertinently stated, we may be judged to be copyists, when, as a matter of fact, we have been victimised just in the manner described in that note.

Four years ago we published a catalogue, succeeded a few months since by a new edition, in which edition a great deal of the same matter appears again, and some in a precisely similar form as before. It has come to our knowledge that this old catalogue which we omitted to register has been largely copied by a firm who have not scrupled to cut out page after page, sending them to their printer to be set up as original matter, embodying them into their own catalogue. Our new edition, which we have taken the precaution to register, was issued a few months before the above-mentioned copy, and it seems to us that the matter extracted is as much taken from the registered as from the unregistered edition.

It would be interesting to know how far a printer is culpable when he is aware that he is setting up matter which has been taken from another catalogue which he himself may or may not have actually printed.

We do not desire to trespass further on your space, and should not have troubled you with these few remarks but for the reason before stated, that we wish to avoid being considered mere copyists, incapable of compiling an original catalogue.—Yours, &c., KING, MENDHAM AND CO.

Western Electrical Works, Bristol, December 20, 1887.

THE LIGHTING OF WELLINGTON, NEW ZEALAND.

At a meeting of the Wellington (New Zealand) City Council the following report was presented by the Mayor on the question of lighting the city by electricity:—"In fulfilment of a promise made to the Council in connection with the electric lighting of the city, I recently visited Reefton with a view of gathering such information as might assist us in coming to a decision. The installation at Reefton is not yet in work; it is principally for domestic lighting of houses and business places. The Swan incandescent lamp is adopted. The scheme is a private speculation of a company with a capital of £5,000. The motive power is water supplied through a 50 horse-power turbine, the cost of bringing the race is about £2,300, the light is supplied by a single dynamo of 520 candle-power, the cost of dynamo and turbine with wires laid on to houses is about £1,800. It had been intended to lay the wires in the main street underground, and in other streets to carry on poles, but it is probable that the whole wires will be carried on poles, as it is considered less liable to injury than if laid underground. Private consumers have to provide their own fittings, the company charging for supplying the light for each lamp of 20 candle-power the sum of £2 per annum, the man being at liberty to use it from dark to daylight. In order to be able to see if the above information will be applicable to Wellington, there are three points to be considered. The first is—Can water be given for motive power? Second, Is water-power the best motive, all things considered? The third point is, Is the estimate of £2 per annum for 20 candle-power lamps reliable? To the first it may be pointed out that we have a large amount of water running to waste, for although there was some scarcity of water last summer, it was not from lack of water, but from leakage, which is now being repaired. Even then there was a supply of 98,000,000 gallons in Karrori, which will be available with the more high-level pipes which are now being laid. Even when water was short it must be remembered that the consumption was over 100 gallons per head, which is about five times the amount consumed in English towns, where there is a proper system of waste prevention. The water would be drawn off at night when little or no consumption would be going on; and it must be remembered that when the greatest amount of light would be required would be in winter, when both reservoirs are flowing over. Furthermore, if required, it is known that the Wainui supply can be doubled at not a great cost; and, further, the fact that the water supply has cost £215,000 shows it is of the utmost importance to make the best use of it. The above is, I think, sufficient to show that there is no difficulty as to water supply for power. The next question for consideration is whether £2 per annum per 20 candle-power is reliable. I am able to test this from other sources. At Broomhill, in England—where one of the most complete plants in the kingdom has been laid down, costing for engine, boilers, dynamo, batteries, buildings, &c., £6,000—accurate accounts have been kept for several years of every penny spent on the light. They have brought the electric light down to one-seventh 1d. per hour for 20 candle-power lamp. A six-foot gas burner costs ½d. per hour with gas at 3s. 6d. per 1,000, the electric light thus proving nearly twice as cheap as gas at 3s. 6d. per 1,000. It is expected to be brought further down still to one-tenth of a 1d. per hour. I am informed by an engineer who was engaged in fitting up Taunton, in England, that the charge is for a 1,200 candle-power arc light 2d. per hour, and incandescent lamp, 20 candle-power, £1 per annum. To sum up, a 20 candle-power lamp would cost Reefton £2 per annum; Broomhill, £1 1s. 8d.; Taunton, £1. In each case wear and tear and profit are included. In Wellington, according to the Corporation books, the mean of 40-meter lamp shows that it costs for gas alone £3. 17s. 9d., but if we add breakage, wear and tear, the cost is £6. 10s. each lamp. In 1872 it cost to light Brooklyn £145,000, with a population of 400,000. In 1887 the cost by electricity is £85,000, although the population increased to 700,000. From what has been stated it is fair, I think, to conclude that by using our resources we can thoroughly light the city from end to end without extra annual charge. All will agree that the city is badly lighted, taking all its surroundings into consideration, especially when we consider that sometimes from Saturday night to Monday over 400 persons arrive by sea. Our shortness of funds compels us to spend less on lighting than any other city in New Zealand, as the following will show:—Auckland, £2,112; Christchurch, £2,600; Dunedin, £2,730; Wellington, £1,650. To light the city fairly would take at least 300 lamps, and to give, say, two hours more of gaslight than we have now would cost at our present rates per lamp £2,650 per annum. By using water-power in the manner I have indicated to light the city by electricity, I estimate the same amount of light can be got at an annual charge of about £1,650, thus saving about £1,000. The success of lighting the city will partly, if not wholly, depend on the proper working out of the details and choice of motor; and I might add that Dr. Lemon has kindly promised his valuable advice and assistance in carrying out the matter."

Councillor RICHARDSON moved that the report be accepted. The thanks of the Council, he said, were greatly due to the Mayor for the trouble he had taken.

Councillor EDWARDS seconded the motion, which was carried.

The matter was subsequently referred to a committee, consisting of the Mayor and Councillors Brandon, Richardson, Williams, and Edwards, to collect information and report to the Council.

COMPANIES' MEETINGS.

The Gulcher Electric Light and Power Company, Limited (in Liquidation).

Pursuant to the order of the Honourable Mr. Justice Stirling, made in the High Court of Justice on November 30, meetings of the holders of debentures issued by the above-named Company, and of the creditors of the said Company, as well as of the other creditors, were held at the Cannon-street Hotel on Monday last for the purpose of considering, and if thought fit approving, a proposed scheme of arrangement between such classes of creditors respectively and the said Company (a copy of which scheme accompanied the notice). And if such scheme were approved by the meetings, then for the purpose of electing Directors of the new Company to be formed as mentioned in such scheme.

Mr. D. DE CASTRO (the liquidator) occupied the chair.

The SOLICITOR to the Company (Mr. A. Trinder) having read the notice convening the meeting in the interests of the debenture-holders,

The CHAIRMAN said: Gentlemen, I really do not know that I have anything to say in addition to the information conveyed in the notice. The Company has been carried on by me as liquidator for the last six months, and as far as I can make out we have paid our way, and perhaps a little more than that, for we have paid off some of the debts of the old Company; but, of course, I cannot tell exactly what our position is until we have taken stock. But I have paid off arrears of rent, and also those creditors who could have taken precedence over others, and matters stand really where they were when I met the shareholders last July, I think it was. The scheme that has been laid before you speaks for itself. I presume you have read it through and considered it. If any debenture holder present has any question to ask about the scheme, I shall be very happy to answer it to the best of my ability. The great question will be, no doubt, what amount of support can we get from the debenture holders? I think there are debenture holders representing £8,000, and of this amount £5,000 was advanced by *bonâ fide* investors in debentures. The other £3,000 are debentures held by the Directors, who lent £3,000 to the Company for temporary purposes; so that you may treat the debentures as being of two classes—those that represent money invested as a permanent security, and those that represent money which was lent for temporary purposes. I think the holders of the debentures probably will find £4,000 towards the £20,000 required. I think that the creditors that I have spoken to will probably find another £4,000 or £5,000, and I am of opinion that there are some shareholders and absolute outsiders who will make up what I have had practically promised to me, if the scheme succeeds—namely, about £10,000. Then we would want another £10,000, which would have to be found somehow. That could be realised by an appeal to the public or to the shareholders unless the debenture holders of the £5,000 like to increase their stake. The Company is going on fairly well even in its present state of liquidation, and the prospects of the business, if it is carried on, are very good indeed. I can tell you that the orders that I have in hand at the present moment as liquidator amount to nearly £1,700, and that those which we feel pretty confident of being able to obtain—in fact, quite confident of being able to obtain if we go on—amount to nearer £8,000. The amount due from the customers has increased from £3,365, when I took matters in hand in July, to £3,667 at the present moment. There is, in fact, a variety of little details showing progress that I do not want to take up your time by going into at the present moment.

Mr. OGLE questioned whether the position of the Company had recently improved. The last time he attended a meeting was when they were taking power to issue debentures, and he remembered one of the Chairman's statements at that time was to the effect that the debentures were fully secured—that there were sufficient assets of the Company to pay the debentures, come what might. From the Chairman's statement now he calculated that the debentures would not be fully covered.

The CHAIRMAN said that, assuming the debentures to be good, they were very amply covered. But the question had been raised as to whether the debentures had been validly issued; but he did not think there was anything material in it. At any rate that question had been raised, and might have to be fought out. Assuming, however, the debentures to be good, the property was worth from £10,000 to £12,000 on a forced sale.

Mr. OGLE: What is the amount of the debentures?

The CHAIRMAN: £5,000 of the first issue and £3,000 of the second.

Mr. OGLE: What are the prior claims?

The CHAIRMAN: The prior claims I have paid off. There will be nothing now.

Mr. OGLE: The rent too?

The CHAIRMAN: I have paid off the rent. The only kind of creditor who had a sort of priority was one who gave us a machine payable by instalments, and that is reduced to about a couple of hundred pounds more.

Mr. OGLE: Then we may assume that the position is not worse than when you took power to issue the debentures? The material point then was that the debentures were fully secured, and that there would be something left to the creditors also on a sale.

The CHAIRMAN: I believe that to be the position now.

Digitized by Google

The SOLICITOR said that the committee estimated that the lowest price that they would get for the Company's assets would be about £10,000.

Mr. OGLE presumed that they looked more to the shareholders and other people than to the creditors to reconstruct the Company by finding the necessary funds.

The CHAIRMAN explained that most of the debenture holders were also shareholders having a large interest in the concern. They were, in fact, the most powerful of the shareholders. They had always assisted the management up to this time, and he looked to them still for support. He looked to them for their own sakes to secure their debentures, and to obviate any possibility of litigation. It was a very tempting thing to solicitors, accountants, and all those who were interested in a good chancery suit to have a substantial basis to work upon, such as the Company's assets offered.

Mr. OGLE: "Wreckers."

The CHAIRMAN would not say "wreckers," but it was a good thing for such people to have a good company with £10,000 or £20,000 to work upon in a case of litigation, and he wanted as much as anyone to avoid the possibility of such litigation and the consequent waste of the Company's assets.

Mr. COTTON wished, in the interests of all concerned, to have a little more information from the Chairman in reference to the doubt that had been thrown upon the legality of the issue of the debentures. Did the objection come from one of the creditors, who, he supposed, would be the parties most interested in upsetting the debentures, and did it apply to all the debentures? He thought that they ought also to be informed of the nature of the doubt.

The CHAIRMAN explained that under the Articles of Association the Directors were not empowered to issue debentures beyond the amount of the uncalled capital for the time being. Thereupon the Directors called a meeting of the shareholders in the Company, and asked them to pass a special resolution to rescind the clause limiting their power, and authorising them to issue debentures for a limited amount, notwithstanding that the whole of the capital which had been issued was called up. The meeting to alter the articles was held on the 10th of the month of May, and the confirmatory meeting was held on the 24th, and the special resolution was registered as such, taking effect on that date. Now, the statute said that there should be 14 days' interval between the two meetings, and it appeared from a decision of Mr. Justice Chitty upon that clause of the Act that there must be an interval of 14 clear days between the two meetings, so that their confirmatory meeting ought to have been held on the 25th instead of on the 24th of the month. That was the exact nature of the objection which was taken up by one of the creditors. The serious question would arise whether it was a creditors' question at all—whether, in fact, it was not a matter between the shareholders and the Directors. In the latter case he submitted that the shareholders had confirmed, or waived, any irregularity by passing the accounts subsequently, and therefore it did not lie in their mouths to object to the validity of the debentures. As to the creditors, it would be submitted, if it were argued, that all that was required to be done to protect their interests was done. The debentures, purporting to be good, were registered; the creditors gave credit to the Company, knowing that that money was in existence, and the money obtained by the debentures was applied to the payment of those very creditors who were taking objection, and that would be part of the argument in defence. Another argument in defence was this—and it would raise a very serious question if it was fought out—that the Articles could not override the Memorandum, which gave the Directors absolute power to issue debentures without any limit at all. There was another kind of objection, but he supposed they all saw the nature of the dispute. It was a most trivial technicality and without a scrap of morality in it.

Mr. OGLE: Did the creditors take objection at the time that the debentures were issued?

The CHAIRMAN: Not at all, which is a material point.

The SOLICITOR said that it was in the interest of the debenture holders and everybody else that the scheme should be successfully carried out, so as to avoid all litigation.

The CHAIRMAN, in reply to a shareholder, said that what he had said had been based upon counsel's opinion, but the point raised admitted of argument in Court. A very material point was this. In his opening statement he mentioned that they were limited in their debenture issue to the amount paid up in the issue of capital. Now, as a matter of fact, they had a lot of unissued capital, which was an argument in their favour. While there was any capital unissued they need not have called the meeting. There were a great many arguments for the defence that the Court in such a case as this would duly weigh in their favour.

Mr. COTTON asked whether, if a debenture holder wished it, he could claim to be paid off?

The CHAIRMAN replied in the affirmative.

The SOLICITOR said the scheme was drawn up so that they might get by it enough cash to pay off the debenture holders. The latter would be asked to support the new scheme by taking shares in it; but if they did not wish to join it there would be no objection to their getting their money returned. Meantime, they were merely asked to sanction the scheme.

Mr. COTTON: What about the arrears of interest?

The CHAIRMAN replied that he had enough money to pay the amount, but he could not do so without the leave of the Court in the face of the legal objection referred to.

Mr. COTTON then formally moved, and Mr. FULSHAM seconded, a resolution authorising the scheme as printed and circulated among the shareholders to be carried out, which was agreed to.

The CHAIRMAN said that at an informal meeting of the creditors and debenture holders, a suggestion was made that the number of Directors should be increased to seven, and a discussion took place upon the question who should be the new Directors. It was decided that there should be two to represent the creditors, two to represent the debenture holders, and the same number to represent the shareholders, and that the six gentlemen selected at the three meetings to be held that day should themselves choose a Chairman, of some position and power, to keep the team in order. The names of Messrs. Henry Grewing and Thomas Lloyd were suggested as the two representatives of the debenture holders.

Mr. WALLACE then proposed that these two gentlemen be appointed Directors in the interests of the debenture holders.

Mr. KELLY seconded the motion, which was unanimously agreed to.

This concluded the business of the first meeting.

There was afterwards a meeting of the shareholders to ask their sanction to the proposed scheme.

The SOLICITOR, having read the notice convening the meeting, said there was one matter that he wished to explain, being solicitor to the liquidator. They all knew that previously a scheme on an entirely different footing had been submitted to the shareholders. After a great deal of trouble on the part of Mr. De Castro the £15,000 proposed to be raised to carry it out was got together; but unfortunately it had been too precipitately gone about, with the result that when the new Company came to consider the actual figures it was found, partly owing, perhaps, to the action of their friend, Mr. Mountain, in very energetically pushing forward the business, that some of the items under the head of cash assets had ceased to be cash assets, and were represented by stock. The effect of that was, that if the scheme had succeeded they would have had a larger amount of stock and a smaller amount of cash assets than appeared at first sight; and one of the Directors, who represented an entirely new element, raised a serious objection. That gentleman thought that the figures were not those that had been put before the shareholders, and that, in his view, the scheme ought not to be carried out. The effect of that decision was that the Directors of the new Company felt a great difficulty in executing the proposed agreement, and it was accordingly never executed. All the money subscribed to it had therefore been returned.

Mr. KELLY then proposed, and a SHAREHOLDER seconded, a resolution pledging the shareholders to agree to the proposed scheme.

Mr. A. J. KING wished before the motion was put to offer a few remarks. In a letter he had addressed to the Chairman he stated that he thought that the payment of 10 per cent. to the preference shareholders, coupled with the decision that anything earned beyond that amount should be shared by the "A" and "B" shareholders in proportion to their capital, was unjust, and hoped that that was not what was intended. It would be wiping out the "B" shareholders altogether. In that case he would be prepared to move an amendment to the resolution. Would the Chairman explain how the thing stood?

The CHAIRMAN said that he was sorry to say that he was not able to explain that the intention of the scheme was in accord with Mr. King's wishes. The idea was to give the preference shareholders—those who found the money to keep the Company on its legs—such an inducement as would cause them to find the money, and the least that could be given to them was 10 per cent. and the additional inducement of sharing with the ordinary shareholders in any surplus earned beyond that amount. The subject had been carefully thought out at great length, and they were afraid that they would not get the money from anybody except upon those terms. Of course, if the shareholders would come forward as a body to find the bulk of the capital, they could dictate their own terms, but unfortunately those who were dictating the terms at present were those who were to find the money. It was found by negotiating with the latter that they would not take anything less than those terms, and he was afraid that easier conditions could not be agreed upon.

Mr. OGLE said that he had found in the companies with which he had been connected that the usual custom was to issue 10 per cent. debentures. A 10 per cent. debenture was worth more than a 10 per cent. preference share. The only company he knew of that differed from that was the Russell Gold Mining Company, which proposed to pay 7 per cent. The only remedy of the "B" shareholders was to be "A" shareholders as well.

The CHAIRMAN: "Hear, hear."

Mr. OGLE was quite satisfied from his own experience that there was no chance whatever of obtaining money at 10 per cent. unless they undertook to give a division of the profits after that was earned.

The CHAIRMAN said he was very pleased that Mr. King had raised the question, because he was quite sure that that gentleman was the last man in the room not to acknowledge that he (the Chairman) had made the best terms he could for the ordinary shareholders.

Mr. KING asked what was the condition of the Company as regarded the past six months' working.

The CHAIRMAN said that they had done more than any other company in liquidation would have done. All through the summer they did quite as much as they did last year. They had not done quite so much in October and November as they did in the corresponding months of last year, but what had been done was done at very much less expense, and the prospects of work if this scheme were carried out were very good indeed, the Company having contracts for at least £8,000 in hand. He had no doubt it would surprise them to learn that they had tendered in the course of the year for *bonâ fide* work amounting to £300,000. He mentioned the fact merely for the purpose of showing the amount of work in the electrical world, a reasonable proportion of which they might expect to secure. He had blown the trumpet of the Gülcher Company so often that he was beginning to get afraid of saying too much about it, but the more he was associated with it the more convinced he was that it was a really sound concern.

The resolution was then put and carried.

On the motion of Mr. OGLE, seconded by Mr. FARMER, Mr. D. De Castro

Digitized by Google

and Mr. W. Wallace were appointed Directors to represent the shareholders at the Board.

A meeting of the creditors was then held, and after the notice convening it had been read by the SOLICITOR,

Mr. JACKSON said that before the resolution asking them to approve of the scheme was put to the vote, he ventured to tell his brother creditors exactly the position in which they stood, because the somewhat voluminous documents which they had had submitted to them might not have been quite understood by all of them. As he had been in communication with Mr. De Castro, and ascertained all the facts of the case, he would endeavour to lay them before the meeting as briefly as he could, and then they could judge for themselves whether it was advisable to adopt the scheme or not. It would be useless to disguise from the meeting or the liquidator of the Company that there were serious questions depending upon it. The debenture holders held documents which, if sound, would entitle them to a claim over the other creditors; but if unsound it was perfectly clear that they were not likely to give up what they supposed to be their rights to anyone without a fight. On the other hand, if the creditors, as they were advised, were right in their contention that the bonds were informal, they were not likely either to hand over the proceeds of the sale of the Company without a fight. Now, a fight was no doubt a very pleasant thing to professional men, who had everything to gain and nothing to lose thereby; but he would be frank enough to say that for all parties concerned this ought to be the last thing they ought to resort to, because it would seriously damage the Company. If there was any *via media* by which they might adjust their respective claims it ought to be followed. Mr. De Castro proposed to start a company which, if he got all the money wanted, would pay all the creditors and debenture holders too. Therefore, *primâ facie*, he (the speaker) unhesitatingly believed that it would be to the interest of the creditors that they should support the proposal. They had been long-suffering creditors, he admitted; and there had been a long delay in getting matters brought to an issue, partly, of course, owing to the long vacation, and that delay was only now, apparently, coming to an end. He urged on Mr. De Castro, however, at an informal meeting, that that gentleman ought to tell the creditors of the Company how long he (Mr. De Castro) intended to prosecute the proposed scheme. If Mr. De Castro would undertake to say, after he had got everything into working trim, that he would be willing to limit himself to a moderate but definite time during which he would make his efforts to carry it out, no doubt the creditors would be better pleased than they would be if they were left in a state of suspense with regard to the matter. If they gave Mr. De Castro an absolutely free hand, they might be no better off six months hence than they were now. He thought that it ought to be the policy of the creditors to consent to the scheme on the understanding that Mr. De Castro gave some such assurance as he suggested, because he did not think that they should go on for an unlimited time.

The SOLICITOR said that if the scheme were approved that day, it had to be technically agreed to by the Court. Then the Directors of the new company would have to draw up their prospectus, and he did not see any reason why it should not be issued immediately after the decision of the Court was obtained, and then it would be for the Directors of the new company to say whether they could or could not, after a reasonable time, get the requisite £20,000. If the Directors came to the conclusion that they could not raise that amount, they would merely have to return such moneys as they received, and the assets of the Company would then have to be sold in the ordinary way. He did not think that there need be any understanding of the kind suggested. All they were asked to do was to approve of the scheme now before them.

The CHAIRMAN objected to having his hands tied in the matter, although he was in favour of doing something or other as quickly as possible, or of winding-up the whole concern. At the same time he believed it would be very unreasonable to go on beyond the end of February.

After a few remarks from Mr. BLYTH and Mr. HEADLAND,

The SOLICITOR pointed out that if the scheme could not be carried out within a reasonable time the parties concerned had the protection of the Court, not to mention the fact that if any individual creditor were aggrieved he had his remedy by taking legal proceedings to bring matters to a head.

The resolution approving of the scheme was then agreed to.

On the motion of Mr. LAMONT, seconded by Mr. BAILY, Messrs. Gustav Binswanger and Howard Lane were elected Directors to represent the creditors.

In deference to the wishes of Mr. Blyth and other creditors, a recommendation to the Directors to the effect that if the proposed scheme of reconstruction was not carried out by the 28th of February next the creditors should be again called together to consider the position or the scheme be dropped was agreed to, and the proceedings terminated.

CITY NOTES, &C.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 9th inst., amounted to £4,756, and for the week ended 16th inst. to £5,052.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY.—This company notify that the coupons due 2nd January next on their Five per Cent. Mortgage Debentures will be paid on and after that date at the banking house of Messrs. Barclay, Bevan, and Co., 54, Lombard-street, E.C. Coupons should be left three clear days for examination.

EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY.—This company notify the declaration of an interim dividend for the quarter ended 30th September last, of 2s. 6d. per share, free of income-tax, payable on the 14th January next.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—It is announced that the coupons due the 31st inst. on the debentures of the West Coast of America Telegraph Company will be paid by Messrs. Barclay, Bevan and Co. The coupons must be left three clear days for examination.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 16th inst. were £4,082, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 15th December are £2,751, as compared with £2,222 in the corresponding period of 1886. The August receipts, estimated at £4,008, realised £4,107.

REMOVAL NOTICE.—The Pilsen-Joel and General Electric Light Company are removing their works and offices to their central lighting station at 4, Stanhope-street, Euston-road.

THE "SANITAS" COMPANY'S TRADE MARKS.—We are requested to give currency to the following:—Reports have been recently published of a case heard before Mr. Justice Kay, in which we (the "Sanitas" Company) applied to obtain the registration of our trade mark "Sanitas" in Class III. (being for "Chemical Substances prepared for use in Medicine and Pharmacy"), and as Mr Justice Kay, upon certain grounds, declined to accede to our application, many persons have concluded that the word "Sanitas" is no longer the recognised trade mark of this company. This is not a correct view of the case. Not only is the word "Sanitas" registered in Class II. ("Chemical Substances for Sanitary Purposes, such as Deodorants, Disinfectants, and Antiseptics") and in a great number of other classes, but further, we have two other trade marks which are registered in another variety of classes. It may further be stated that we retain to the full our common law right against imitations; indeed, so recently as October 27th last an injunction was granted, with costs, by the Chancery Division, High Court of Justice, restraining the defendant, &c., from infringing the company's registered trade mark "Sanitas" by any use of that term as applied to deodorant, disinfectant, or antiseptic preparations, soaps, and such like substances, and from advertising or selling, &c., any such preparations under the name of "Sanitas" or "Sanitant," or any compound or colourable imitation of the word "Sanitas."

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 502.—Vol. XX. FRIDAY, DECEMBER 30, 1887. Price 4d.

NOTES.

It is just a year ago (on Tuesday last) that the great snow-storm fell which wrought such memorable destruction amongst the overhead wires. The condition of the streets of London on Monday, December 27th, 1886 (and, indeed, for many a long day after), was a sight to be remembered for a lifetime. However, the damage has all been repaired by this time, the losses have been pocketed, and the country has been pacified by the assurance that according to the recognised laws of nature (founded on observations extending over at least twenty years) there will not be another such storm for nine years to come. It should, however, be borne in mind that even if another severe storm should return before the period assigned, the wires are in most cases decidedly better prepared to meet the strain than they ever were before—we are speaking mainly of overhead wires in towns. Much was done to improve the condition of the lines after last year's storm; spans were shortened, stouter poles were erected, and stays and struts were increased in number.

There can, however, be no doubt that still more—much more—might be done to increase the security of our overhead wires if the United Telephone Company were granted some such Parliamentary powers in the matter of way-leaves as they are now once more seeking to obtain. It is without doubt desirable to move cautiously in matters of this kind, where the individual rights of property are to some extent involved; but we are of opinion that the United Telephone Company will be able to make out a very good case. It is, for instance, simply intolerable that the owner of a building in one of the busiest parts of the City, by refusing to permit wires to pass *over* his roof, should have the power to cause a very large number of wires to be carried twice diagonally across a wide street. In a case of this nature it is evident that the unsightliness, inconvenience, and increase of risk to the community far outweigh in importance the merely sentimental objections of the individual against wires stretching over, but not supported by, his roof. We are therefore of opinion that, subject to proper supervision, and the right of protest and compensation for actual injury, such concessions as the company seeks may be safely granted.

While writing of overhead wires we may allude again to the remarkable fact mentioned last week in our account of the Brighton Central Lighting Station, that during five years not a single span of wire has ever given way. Some of the credit of this record is possibly due to the excellence of the engineering, but probably still more is due to the difference between the conditions of the telephone and the electric light service. It is well known that the gathering of snow or ice upon the wires is the most frequent and serious cause of their coming to grief. This is, however, impossible in a No. 8 wire conveying a current of 10·5 amperes, the temperature being thereby maintained several degrees above that of the air. Then again, in the electric light service, the number of wires on a single route is very limited and there can be no fear of pulling down the supports.

The price of copper continues to rise, and the speculation which is running it up has now assumed a rather alarming character. A Berlin financial organ roundly asserts that an alliance has been formed between the members of the Société des Metaux on the one side, and the London house of Rothschild —although this is denied—on the other, to buy up every ton of copper that comes into the market before the 1st November, 1888, on the understanding that in the interval none is to be sold below £70. The facts have now to be seriously faced by the electric lighting industry, as it is scarcely possible to hope that prices will return to anything like their former level for a long period to come. This would not be so much a matter for regret if the movement were closely accompanied by a general advance in prosperity all round; but, as things are, the improvement in trade has not yet had time to affect electric lighting very closely. The electric light already labours under sufficiently heavy burdens in this country without being called upon to suffer further for the benefit of a few unscrupulous speculators.

We learn with satisfaction that Mr. Willard E. Case is continuing his researches upon the reversible batteries of the type which (in the autumn of last year) he was the first to make known. A full account of Mr. Case's original heat-cell may be found in *The Electrician* of Aug. 6th, 1886. In this cell the elements consisted of carbon and tin, and chromous chloride was employed as the electrolyte. At a temperature of 60deg. F. the cell has no measurable E.M.F., but at 140deg. F. it attains an E.M.F. of a little over 0·2 volt. When exhausted it, has only to be allowed to cool down in order to regain its original chemical constitution. No hydrogen is evolved during either charge or discharge, and therefore it is

Digitized by Google

ideally possible that a cell of this type should last for ever without renewal of material or any other attention besides the supply of energy in the form of heat. In the form originally described by the inventor it was evident that for certain reasons, of which the smallness of the E.M.F. obtained is the most prominent, the results could not be expected to be of a highly economical, nor even, perhaps, of an entirely practicable character. But attention having once been awakened to the possibility of effecting a conversion of energy of this type there could be little doubt that substantial improvements would be effected. It is only the more satisfactory that the improvements should be effected by the original discoverer of the method.

THE discovery of the chemical reaction upon which Mr. Case's earlier cell is based was made, however, by M. Henri Loewel, and is described in the *Chemist*, Vol. VIII., page 476. A solution of chromous chloride added to stannous chloride precipitates tin, but when the solution is heated to about 140deg. F., the metal is re-dissolved, and the original salts are formed. Chromous chloride is, however, a difficult re-agent to employ, as it readily absorbs oxygen from the air, forming the oxychloride, which is insoluble.

AT present, we have only somewhat meagre details of Mr. Case's new cell, but we understand that chromous chloride has been replaced by chromic chloride (probably for the above-named reason), and that the tin is employed in the form of a liquid amalgam. The precipitated tin formerly rested at the bottom of the cell upon a horizontal plate of carbon. The addition of mercury is therefore probably chiefly with the view of making better contact.

THE low E.M.F. must, however, still be an insurmountable obstacle to the practical success of the cell on any extensive scale, and it is evident that if the direct conversion of heat can be profitably effected in this manner it must be by some different combination of elements. What is wanted, therefore, is a suitable chemical reaction reversible with change of temperature (such change not exceeding the limits of, say, 20deg. C. to 100deg. C.), and capable of yielding, with carbon as a negative electrode, an E.M.F. of respectable proportions. Such cells would form an ideal battery for household use, and would clear primary batteries altogether out of the field, or rather, the house.

IT appears from some statistics recently published that of the 886 miles of tramway lines now worked in the United Kingdom 232 belong to local authorities. The fact is worth noting in view of the early introduction of electrical power in our provincial towns, and its probable adoption by the municipal bodies. The possibilities of utilising the current for electrical locomotion, as well as the electric light, should be a great inducement to assume the powers which some of the towns already possess, and which all may acquire, under the Electric Lighting Act. By generating power in the daytime, the running of the tram lines and the lighting of the streets would mutually assist in cheapening both systems. Every town installation should take account of this contingency.

THE *Daily News* quotes a statement to the effect that during the last twenty years "more than one hundred English and French patents for perpetual motion have been obtained." That is to say, the Governments of these countries have enriched themselves to this extent out of the pockets of so many fools and dupes. What a satire on the Patent Laws!

THE report of the tests carried out at Cincinnati on the cost of lighting the railway station by gas and by electricity (a copy of which will be found elsewhere) is a curious document, though perhaps a trifle too vague and obscure to repay any very serious criticism. The fact that some of the Edison meters were found to register backwards is, however, a matter of some importance, especially to the shareholders of the companies employing that system. The reporter was, moreover, informed that the phenomenon "is not unfrequent," which, as he justly observed, "seems strange." But the company is not to be baffled by a discrepancy such as this, and it appears that the inspectors are instructed to note the difference between the weights of the two plates without troubling themselves as to the (purely theoretical) distinction between cathodes and anodes.

IN the third edition of Sir David Salomons' work on the "Management of Accumulators," the author (on p. 105) gives the following definition of Edison's meter—"A thing of the past, depending upon the deposit of some metal." We are, unfortunately, a little doubtful as to the immediate accuracy of the first part of this description, inasmuch as we are under the impression that this apparatus is still extensively employed by the Edison Company of the United States; but in the light of the statements alluded to above there can be little doubt that Sir David's description will sooner or later be perfectly accurate.

AS to the "deposit of some metal," which appears at present somewhat erratic, we suppose the balance is made up on the settlement of the account. But if these complaints have any foundation, it is perfectly clear that the error is entirely against the company. As we recently had occasion to remark in our articles on the Brighton installation, the Edison plan, by which a fraction only of the current supplied is measured, can be accepted as little better than a makeshift at the best.

WHILE writing of coulomb-meters we may note that our contemporary, the *Electrical World* of New York, describes an addition to the Forbes meter, which has been introduced by Mr. R. M. Hunter as an "improvement." Mr. Hunter has observed that in the original apparatus no arrangement exists for giving warning in case the rotation of the vanes should cease while the current was on. By an ingenious device, involving the addition of a second set of vanes, it is arranged that in the event of the first set coming to rest the motion of the second set closes a relay contact, which immediately cuts

Digitized by Google

the installation out of circuit. We fear, however, that Mr. Hunter's suggestion is not of a very practicable character. It would be rather hard on the consumer to cut him off because his meter went wrong by accident, and on the other hand if the first set of vanes were tampered with it would be equally easy to stop the action of the second.

For electric lighting installations, a current indicator or volt indicator is generally quite as useful in regular work as an ammeter or voltmeter. It is scarcely necessary to explain that by the term indicator is meant an apparatus which will show whether the volts or amperes are or are not at the normal value, and, if not, in which direction they are at fault. Such an instrument has only to be calibrated for one particular value, and ought, for that reason alone, to be much cheaper than a meter. Moreover, as they are only intended to be used at one particular current strength—whether indicating volts or amperes—there is no objection to the employment of soft iron. We recently described one simple form of current indicator, which is in use at Brighton, and this week we describe an instrument of the same type which has for some time been employed by the Anglo-American Brush Company.

Probably some use might be found for an alternating-current volt indicator. The principle of induction current deflections, which has recently been investigated by Dr. Fleming in this country and by Prof. Elihu Thomson in America, would obviously lend itself to this end. (On the last-named subject see *Electrician*, May 6th, May 20th, and June 10th, 1887.)

Some exception has been taken to the explanation given by the Secretary of the Society of Telegraph-Engineers and Electricians in respect to the Cloak Room arrangements on the occasion of the President's *conversazione*. If it were a mere question of fact, we might of our own observation admit the inadequacy of that explanation; and we should certainly contradict the "chief porter," if he were speaking as a servant of the Institute of Painters in Oil Colours. But on this occasion he was not acting in that capacity; and we invite our friends to remember that whatever inconvenience fell to the guests of Sir Charles and Lady Bright, the annoyance caused to themselves as our entertainers must have been still harder to bear.

Our New York letter had not come to hand this week up to the time of going to press.

Cable Repairs.—The cable between Trinidad and Demerara has been successfully repaired.

Theatre Lighting at Edinburgh.—The Lyceum Theatre at Edinburgh was lit by electricity for the first time on Monday evening.

Colliery Lighting.—The Ffrwd Colliery, near Wrexham, has been lighted throughout by electric light. The installation has been carried out by Mr. Charles Lever.

Dynamo Award at the Adelaide Exhibition.—Messrs. Crompton and Co. have received an award of the first order of merit for their dynamo machines exhibited at the Jubilee Exhibition at Adelaide.

Mill Lighting.—The Hope Paper-mill, Cefn-y-Bedd, North Wales, has been lighted throughout by electricity. The dynamo has a capacity of 5,000 watts, and is driven by water-power. The installation has been carried out by Mr. Charles Lever.

American Telegraphs.—A petition has been filed at Washington for the incorporation of the Postal Automatic Telegraph Company, which intends to establish a line across the Continent from New York to San Francisco. The capital is £600,000, with power to increase it to £4,000,000.

China.—The *Etoile Belge* states that the Van Rysselberghe system of simultaneous telephone and telegraph working is to be carried out upon the line between Shanghai and Tien-Tsen. The Chinese officials were much astonished and delighted with the experiments shown them by M. le Baron Satorine.

Berlin.—The General Company of Electricity of Berlin, with a fully paid-up capital of £250,000, has issued £350,000 of additional shares at a rate of 122 for 100. Forty thousand pounds' worth were taken beforehand by MM. Siemens and Halske, and the rest is subscribed for several times over, all fully paid.

Bradford.—The Electric Lighting Scheme.—The sub-committee of the Gas Supply Committee, who are charged with the duty of carrying out the electric lighting scheme, have passed a resolution in favour of calling in "as a consulting adviser in connection with the scheme the most eminent authority on the subject whose services can be obtained."

Waterford.—It may be remembered that when the Waterford Corporation entered into a contract with Messrs. Laing, Wharton and Down for the supply of a Thomson-Houston plant for street lighting an oil lamp was adopted for the more unimportant streets and thoroughfares. We are now informed that "these oil lamps have been found so unsuitable that the whole lot are now discarded."

Lighting Buoys by Electricity.—An attempt is to be made to light some of the buoys in New York Harbour by incandescent lamps supplied with current from the shore. We shall be pleased to hear of the success of this scheme, but fear that it will encounter difficulties of the character to which we referred last week in connection with the attempts to establish telephonic communication with buoys.

The Dublin Scheme.—In a paragraph from a Dublin journal quoted in our last issue the scheme which has received the approval of the Town Council was spoken of as having been drawn up by the City Engineer. As a matter of fact, and, as our readers have already been informed, the plans and estimates were drawn up by Mr. E. Manville of the United Electrical Engineering Company, Albert Embankment, S.E.

Government Legislation and the Telephone in Italy.—The Roman journal *Bollettino delle Finanze, Ferrovie e Industrie* of December 25th, states that the Minister of Public Works has formulated a project of law for regulating the construction and working of the telephone lines. The bill is reported to be framed upon the report of the committee appointed by the late Minister of Public Works to consider the subject.

Paris.—Some French engineers and electricians are indulging in pleasing visions as to the possibility of obtaining motive

Digitized by Google

power in Paris for 350,000 eight candle-power lamps, or 8,000 arcs of 2,000 candle-power (besides obtaining a splendid water supply) by means of a high-level canal from the lake of Neuchâtel, in Switzerland. The project is at present quite in the nebulous stage, but we shall hope to hear more of it some day.—M. Santon has given notice that when the Budget for the ensuing year comes before the Municipal Council he will move that a sum of 1,000,000f. be set apart for the introduction of electric light by the Municipality.

Telegraph Classes at Birmingham.—The annual distribution of prizes and certificates in connection with the Birmingham Postal Telegraph Science Classes took place on the 21st inst. in the school attached to Carr's-lane Chapel. Councillor M. Pollack (mayor) presided, and there was a good attendance. The annual report stated that 54 students joined the science classes at the commencement of the session, and were distributed in classes as follows:—Technical telegraphy, 29; magnetism and electricity (advanced), 13; elementary, 20. Five sat for examination in technical telegraphy and two passed, one in the honours stage and one in the ordinary stage. Several also passed in magnetism and electricity.

Electrical Engineering in the United States.—At the meeting of the Mason College Engineering Society, Birmingham, held on Wednesday, the 7th inst., Mr. Edward L. Joseph read a paper on the interesting subject named above. The author dealt with the various branches of the science as applied in the American industries, and gave a good idea of the various electrical companies and the business they are doing. He congratulated English electricians on the fact that nearly all the instruments of precision and other delicate work used in the States are of English make. The interest of the paper was enhanced by the fact that Mr. E. L. Joseph has spent considerable time in the States, and was able to speak with practical knowledge of the subject.

A Long Wire Span.—*Indian Engineering* says:—"A remarkable engineering feat has just been carried out in China in the face of unusual physical obstacles. This was the stretching of a steel cable of seven strands across the Luan river by Mr. A. de Linde, a Danish Civil Engineer, aided only by unskilled Chinese labour. The cable is strung from two points 4,648ft. apart. The height of one support is 447ft. above the present level of the river and the second support 737ft. above it. The vertex over the water is 78ft. The Chinese cable is the longest but one in the world. The telegraph air cable across the Kistna has a span of 5,070ft.; two similar cables cross the Ganges, one 2,900 and the other 2,830ft. A third line of 1,135ft. crosses the Hooghly, and in the United States there is one over the Missouri of 2,000ft."

Electrical Heating.—Increased attention is being paid to the employment of electricity for the distribution of heat. Dr. W. Leigh Burton (of Richmond, U.S.) has recently introduced an electrical heater, which we understand the Edison Company of the United States are not unlikely to adopt. This heater consists of a fine platinum or German silver wire, bent into a loop, and covered with fireclay. An electric stove of a different type was recently described and illustrated by our contemporary, the *Electrical World* of New York. This apparatus is modelled on the lines of an ordinary gas stove. It consists of a row of incandescent lamps placed in front of a burnished reflector in such a way that the lamps themselves are invisible, while the heat may either be thrown forward into the room or may be concentrated in an upward direction when it is wished to use the stove for culinary purposes

Progress in Austria.—A correspondent of *Industries* states that, though the central station in Salzburg has only been started a few weeks, the demand for light is rapidly increasing, and the supply of current is already five times as large as it was at starting.—Neuhaus, a town in Bohemia, has also received an installation of arc lamps, overhead conductors being employed.—Next year there will be a Trades Exhibition in the Rotunda, and as it is intended to keep the exhibition open in the evening, a liberal use of electric lighting will be made. The interior of the buildings will be lit by various local firms, whilst the grounds and approaches from the Prater will be lit by the Berlin Allgemeine Electricitäts Gesellschaft. The Vienna firms have approached the Minister of Commerce with a request to take over the installation which they are going to put up, as a permanent feature of the building. This proposal he has promised to consider, provided the cost of the installations be moderate.

The Phœnix Fire Office Rules.—The eleventh edition of these rules has now been issued. The principal alteration since the last edition is the addition of the following important clause in Rule 19 dealing with transformer installations:—"It is preferable that a transformer be so constructed that a leak between primary and secondary coils is rendered impossible. When, however, this is not the case, then the secondary work might be protected by an approved automatic apparatus (or arrangement) at or near the transformer, so that in the event of the difference of potential between the secondary conductors and the earth rising at any time to 400 volts, then the apparatus will instantly act and cut off the current. These recommendations are not obligatory at present, except in those particular instances that may be deemed necessary by the Inspector from the Fire Office." A clause almost identical with the above has appeared already in an earlier edition, but it was afterwards decided to withdraw it for a time until further experience had been gained. It will be seen that the clause has not yet been made obligatory.

The Telephone in Canada.—The following are the latest available statistics of the telephone in Canada:—

Cities.	Pop.	No. of subs.	Rates.
Baltimore	333,000	1,965	$80
Boston	594,000	2,450	120
Cincinnati	285,000	2,714	100
Cleveland	161,000	1,886	72
New Orleans	216,000	1,481	96
Pittsburgh	249,379	1,727	190
Detroit	116,000	2,363	72
Paris	2,236,000	4,500	120
Montreal	200,000	2,000	50
Toronto	100,000	1,900	50
Hamilton	43,000	760	37

From the above it will be seen that Montreal, with a population of 200,000—or less than one-tenth the population of Paris—has almost half as many telephones, with the prospect, as soon as the new company gets into operation, of a largely-increased number. In Montreal there is one telephone to every 200 inhabitants, in Toronto one to every fifty-three, in Hamilton one to every fifty-seven, and in Paris one to every 4,946.

German Dynamo Patents.—Messrs. Siemens and Halske, of Berlin, recently applied to the German Patent Office for the protection of a type of dynamo with internal poles. The application was opposed by Messrs. C. and E. Fein and also by the Helios Company, of Cologne, on the ground of prior use. The Berlin correspondent of *Industries* mentions that this protest has been supported by the Patent Office on the following grounds: "There have been prior publications, notably Patent No.

Digitized by Google

13802, covering the principle of internal magnets placed radially, and the manner of supporting the external armature laterally has also been anticipated in Patent No. 13158. Although these designs have previously been chiefly used for alternate-current machines, it cannot be contended, with the present general knowledge of dynamo electricity, that the application of the design to continuous-current machines is a patentable novelty. Moreover, such application has already been forestalled in Patent No. 19265." This decision will show how very strict the Patentamt is in dealing with inventions for which patents would be granted in England as a matter of course.

The Oerlikon Plating Dynamo.—The following figures relate to one of five 50-unit machines recently built at the Oerlikon Works to the order of the Società Elettrometallurgica of Turin. The original order was for one machine only, with the specification that it should be capable of running continuously, with a stop of only five minutes in each 24 hours. The machine not only met this requisition, but it was found that after 14 hours' continuous running on full load and long after stationary conditions of temperature had been reached, the following conditions were observed :—

Temperature of armature	140° F.
„ „ field-magnets	85° F.

The following are the details of these machines :—

Tension at terminals	115 volts.
Current	440 amperes.
Output	5,600 watts.
Electrical efficiency	95 per cent.
Total weight	14,700lb.
Field Coils.	
Length of wire	15,500ft.
Diameter of wire 3 millimeters, or	0·118in.
Sectional area of wire, 7·069 sq. mm., or	0·109in.
Resistance	11·10 ohms.
Current	10·36 amperes.
Turns	3,370.
Ampere turns	34,913.
Watts lost	1191·4.
Ampere per 1 sq. mm. of section	1·46 ampere.
Armature.	
Axial length	21·6in.
Diameter	23·6in.
Total length of wire	476ft.
Total weight of wire	223lbs.
Sectional area 78·54 sq. mm., or	0·122 sq. in.
Resistance	0·0075 ohm.
Amperes per 1 sq. mm. section	2·8 amperes.
Watts lost	1,525.

The Cost of Central Station Lighting.—A correspondent of *Industries*, signing himself "Contractor," writes the following letter in criticism of the recent article in that journal on the cost of central station lighting, an abstract of which appeared in our issue of the 9th inst. :—"Your article will be read with great interest by many electrical engineers and others interested in electrical subjects. On reading it over I, however, notice that you have, as is usual in such calculations, entirely omitted to consider the question of how your income is to be obtained. In your third column you state most definitely that you provide energy for 60,000 60 watt lamp-hours daily throughout the year. If we suppose that you sell your electricity at 8d., which price has been settled as the lowest that is likely to yield a return in London, you will find that the above supply will yield a gross income of £43,750 per annum. After that, you state that the supply will be taken through 150 transformers of various sizes, from which we must understand that each consumer will have his own transformer, and that the average annual payments that will be obtained from each consumer for electricity supplied will be £290. Now, it is needless to point out that this can never be the case over any extended area of supply ; that, in fact, it is probable that the average maximum sum that you can expect the public to pay for lighting an ordinary London dwelling house or shop will be from £20 to £30 ; and if we take £25 as a mean, it follows that to produce the above income 1,750 houses must be connected to the system, with a corresponding number of transformers, and length of house frontage and of distributing mains. I should have little difficulty in proving to you that under such conditions the present temporary expedients of overhead wiring and house connections, which appear so favourable to the cost of the alternating transformer system, are as inadmissible for this as for the battery transformer system. The increased number of transformers, house connections, and cost of underground distributing mains would then so greatly alter the comparative table of cost which you furnish, that instead of the cost for lights used simultaneously being about £6 and £3 respectively, it will be about £5 for both systems, and that this sum would cover five lights fixed, so that each light fixed would cost about £1."

Telephony in Austria.—A correspondent writes us from Vienna as follows :—"Because in Austria there are about 3,000 subscribers only to telephone exchanges it is constantly said that Austria is behind other States in this respect. Of the 3,000 about 1,000 are in Vienna. It is a question if there could not be more there, but as business is very bad in Austria, especially in Vienna, it certainly does not seem likely. Why are there not more in Austria? is the question, and the answer is simply because there are so very few towns of any size, and still fewer commercial or manufacturing towns; and where there are no towns telephone exchanges are not wanted. Austria is an agricultural country, and cannot be called a manufacturing or trading country. On the other hand, those towns which are commercial have already telephone exchanges, and in them the number of subscribers will compare very favourably with those of any other towns of similar size in Europe; and the charges still more so, whilst the service is known to be excellent. The following table will prove that most of the towns outside Vienna are well supplied with telephones, especially in proportion to the number of inhabitants :—

Prag	200,000	inhabitants,	516	subscribers
Trieste	120,000	„	427	„
Lemberg	100,000	„	226	„
Graz	98,000	„	222	„
Czernowitz	45,000	„	101	„
Pilsen	38,000	„	111	„
Reichenberg	28,000	„	232	„
Bielitz	13,000	„	137	„
Linz	41,000	„	130	„
Brünn	83,000	„	250	„

The first eight of these are worked by the Telephone Company of Austria. The charges vary, according to the size of the town, from £5 to £7—a very low charge. Out of these on'y Prag, Trieste, Reichenberg and Bielitz can be called commercial or manufacturing towns, to which Brünn must also be added. No doubt there is further room for increase, and the Austrian Government have wisely decided to open exchanges in the remaining towns, and it is understood that at the beginning of next year exchanges are to be started in Krakan, Salzburg, Innsbruck, Marburg, Moran, Wiener Neüstadt, Baden, Gablenz, Karlsbad, Teplitz, Troppan, Laibach, Görz, and others."

SOME ENGLISH CENTRAL LIGHTING STATIONS.

I.—BRIGHTON.

(Concluded from page 153.)

(Concluded from page 153.)

Method of Testing Incandescent Lamps.

A very simple method of testing incandescent lamps is in use at Brighton. It consists in comparing the *colour* of the hot filament with that of an albo-carbon gas flame. This is done, not by a direct comparison of the lights, but by comparing their individual shadow-tints. The test may be thought a somewhat rough and ready one, but a careful series of experiments carried out by Mr. Wright some two years ago led him to believe that, so long as the operator has a good eye for the detection of minute variation of tint, the test is really capable of very great accuracy. These experiments were conducted with lamps supplied by four different makers, namely, Edison-Swan, Lane-Fox, Woodhouse and Rawson, and Swinburne, and the conclusion was arrived at that when burning at the same colour (that is to say, at the same temperature) the consumption of energy is at the rate of 3·6 watts per candle for each lamp. The total candle power is therefore obtained by dividing the watts by 3·6, and under the conditions of the test it is known that the lamps are burning at the same number of watts per candle power.

The Method of Working.

The following is the daily routine of the station:—During the hours of daylight the small Hornsby engine and the 16-light dynamo are sufficient to supply the requirements of the town, and the whole of the circuits are during this period connected together in series. Towards evening steam has been got up, and one of the large Fowler engines is ready for work. It is now necessary to divide the circuit into two parts, and to place the heavier portion on one of the larger dynamos, leaving the small machine to work the lightest circuit. We will explain presently how this is done. As more lamps are switched on, the E.M.F. at the terminals of the second machine gradually rises, until the shunt regulator reaches its limiting position; at this point a bell rings as a signal for increased E.M.F., as already explained in describing the method of regulation. This increase might, of course, be obtained by increasing the speed of the engine, which is supposed to be running at half speed at present. But there are still four machines standing idle, and the speed of the engine will not be increased until each of those machines has been brought into service. The previous operations are therefore repeated, a third machine is started, the circuit is again divided, and the E.M.F. at the terminals of each machine remains for the time being within the limit attainable at the particular rate of driving. This series of operations is repeated until all five machines are at work, each on its own circuit; after this condition has been reached the next signal for increased E.M.F. is responded to by increasing the speed of the engine. The engine is made to govern at the altered speed by altering the tension of the governor spring. The engine is usually started at forty revolutions, and the speed is increased about one revolution at a time, until the maximum of eighty-five revolutions has been attained. Later on in the evening the lamps begin to diminish in number, and the operations just described are successively reversed, until the circuits are again all in series and the Hornsby engine again takes charge of the all-night work.

Switching Over.

The whole of the operations above described are carried out not only without interruption to any of the circuits, but also without producing the slightest perceptible variation or flicker in any of the lamps. The procedure is as follows:—

The machine to be introduced is first started at the proper speed, with a variable liquid resistance shunt on the armature, and with the field shunt regulator at its lowest position—that is, with a shunt of small resistance. The machine being in this condition it is then brought into the circuit of the dynamo which is already at work. This is done in the usual way, by first connecting the machine with two terminals on the switchboard, through which the current is passing, and then withdrawing a plug between them. The current is now passing to the line through the armature and shunt of the second machine; but the latter is generating very little E.M.F., because its field is fully shunted. The next proceeding is to gradually withdraw the shunt from the armature until the full current is passing through it. The shunt upon the field can now be allowed to rise, and the automatic regulator coming into play the potential is adjusted and maintained at the proper point.

The two machines are now working together in series upon the looped circuits. The separation of the lines into two distinct circuits is effected by so adjusting the automatic regulators that the E.M.F. produced by each machine is sufficient to drive the current through the circuits each is going to supply. When this is done the circuits are separated by simply turning an ordinary cut-out switch.

When shutting down for the night, the same series of operations can be performed in reverse order; but this is not usually done, as the necessity of avoiding any interruption to the light is absent at 1:30 a.m. Although somewhat complicated to describe, it will easily be seen that the system adopted is really very simple and straightforward, and provided no blunder is made by the manipulator, the operation can be performed with ease and certainty.

Cost of Production.

We have already mentioned that the consumers are charged at Brighton at the rate of 1s. per unit, or kilo-watt-hour. This is of course a very good price, and is, in fact, one of the highest on record, but Brighton is a wealthy place and can afford to pay for a luxury. The cost of production does not, however, leave a very large margin of profit on the capital outlay. The actual figures have been very carefully worked out, the observations extending over a long period, and the exact cost is now known to a fraction. It amounts to 9·313d. per unit. This result may, perhaps, appear a little uncomfortable in the light of the fact that there are schemes already in progress elsewhere in which it is proposed to supply electricity at rates not much exceeding half what it costs at Brighton. The consideration that will probably first recur to the reader is that the dynamos at Brighton are of old and somewhat inefficient type; and, next, it will be remembered that the whole installation consists at present of only some 1,500 lamps. The following detailed analysis of the expenditure enables us, however, to obtain a clearer view of the relative importance of these and other considerations:—

	d.	Per centage.
Wages	2·580	27·7
Coal	2·180	23·41
Water	·192	2·06
Oil and Waste	·290	3·12
Carbons	·338	3·63
Office Expenses	·581	6·23
Salaries	1·260	13·53
Rent and Taxes	·725	7·78
Repairs	·287	3·08
Petty Disbursements	·030	0·86
Depreciation	·800	8·60
	9·313d.	100·00

It is not our intention to enter upon a full discussion of this table, but there are one or two points which may be dwelt on briefly. It will be noted that depreciation is entered in the second column as 8·6 per cent., but it will be seen that this is not the average rate per cent. which is charged upon the capital account, but only the relative value of this item in the actual cost of production. Next it will be seen that the consumption of coal and water, which are the only items varying directly with the total output, amounts to no more than 25 per cent. of the total. This is a point of considerable importance. It shows, for one thing, how easy it is to over-rate the advantage of high commercial efficiency in dynamos for central station work. An increase of 10 per cent. in the efficiency of

Digitized by Google

the machines would in this case affect the total cost of production by only $2\frac{1}{2}$ per cent., or, in other words, it would reduce the cost of one unit from 9·313d. to 9·08d. Mr. Wright holds the opinion very strongly that mechanical strength and solidity of construction, together with facility for effecting repairs, is to be preferred in a dynamo machine before high efficiency of conversion. It is for these reasons that he has been content to run the station with the old Brush machines, though, as we have already hinted, preparations are in progress for replacing them wholly or in part by modern alternate current dynamos.

With this chapter we close our account of the Brighton Central Lighting Station for the present, but we shall return to the same place in a few weeks' time in order to describe the alternating current distribution which Mr. Wright is now introducing.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY A. E. KENNELLY.

CHAPTER V.—*Current (continued).*

(Continued from page 155.)

46. With submarine and subterranean conductors, however, the conditions are such, for reasons we need not at present enter upon, that the variable period is generally very much greater than that for overhead wires of the same length. The Thomson recorder shows this very clearly, for supposing that the current received on a long cable arrived immediately at its full strength, and that the coil and siphon responded immediately—that is to say, had no retarding friction or inertia—then the received signals would always be as shown in Fig. 16, and the application of a permanent current would produce a right-angled out-

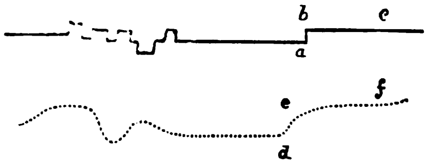

FIG. 16 AND 16A.*

line like *a b c*; but owing to the gradual rise and fall of the current during the variable periods preceding and succeeding an application of the battery to the sending end, the slurred signals and curved line, *d e f* (Fig. 16A), are actually received. On a long submarine cable the current which passes from the cable to earth one second after the application of the battery to the distant end may be perhaps only 40 per cent. of the full ultimate current. After three seconds the current will probably be very nearly at its full strength, but many seconds must elapse before the maximum can be said to have been reached.

47. It is clear, therefore, that it is incorrect to speak of the velocity of electricity. If, for instance, an indicating instrument be set at the receiving end of a line, and the time which elapses between the application of a battery at the sending end and the indication of this instrument be measured, we can say that this signal required that particular interval of time to be produced over that distance of line under those circumstances; but by altering the sensitiveness of the instrument and the form, dimensions, and position of the line we can make the time required to transmit that signal as great or as small as we please; and, so far as is known, there is no time of transmission over any given distance so short that by still further altering the conditions it might not be made yet shorter, so that under these circumstances it is impossible to assign any velocity as inherent to electricity, like that which we attribute, for example, to light in its passage through space.

* The curve *d e f* is accurately given on a larger scale at p. 329, Jenkin's "Electricity and Magnetism," 2nd Edition.

48. After the variable period has passed, however, the current in a circuit will continue to flow, under the control of much more simple laws, at a constant rate, so long as the conditions of that circuit remain constant. The strength of current is proportional to the conductivity of the circuit when the E.M.F. in that circuit is constant. This almost follows from our conception of the term conductivity, for if a certain circuit offers a given degree of facility to the passage of a current supplied by a constant E.M.F., then it follows that by doubling that degree of facility we double the current flow, and if we make the conductivity 0·2, 0·9, 15, or 1,000 times what it was at first, we shall with the same E.M.F. obtain 0·2, 0·9, 15, or 1,000 times our first current.

49. When the conductivity of a circuit is constant, then the strength of the current which flows through it is proportional to the E.M.F., just as the flow of water through a pipe is proportional to the difference of level or "head," which drives it. So that by doubling the E.M.F. in a circuit of constant conductivity we double the amount of current flowing through the circuit, and if we make the E.M.F. 0·005, 0·7, 16, or 1,000 times what it was at first with the same conductivity, we shall get 0·005, 0·7, 16, or 1,000 times the original strength of current.

50. The unit strength of current is called the *ampere*, after the French physicist of that name. It is the current which flows in the circuit of unit conductivity containing the unit E.M.F. That is to say, one volt in a circuit of one mho generates a current of one ampere. It follows, therefore, from what we have seen in paragraph 48, that the current in a circuit of one volt and two mhos would be two amperes, with one volt and 50 mhos, 50 amperes; also by what follows in paragraph 49 that with two volts and 50 mhos, it would be 100 amperes, with 50 volts and 50 mhos 2,500 amperes, and in the same way with $\frac{1}{2}$ a volt and $\frac{1}{4}$ of a mho $\frac{1}{8}$th of an ampere; so that in all cases the current in a circuit is found in amperes by multiplying the E.M.F. in volts by the conductivity in mhos. This simple and vitally important statement of facts is named after its discoverer, Ohm's law. Since, however, we have seen in paragraph 30 that the conductivity of a circuit is the same in mhos as unity, divided by the number of ohms in that circuit, we may to find the current multiply the E.M.F., not by the number of mhos, but by their equivalent unity divided by the ohms in the circuit's resistance; in other words, divide the E.M.F. by the resistance. Thus we have seen that a circuit containing five volts and of 0·025 mho conductivity, would sustain a current of $5 \times 0{\cdot}025$, or 0·125 amperes. But the resistance of the circuit would be $\frac{1}{0{\cdot}025}$, that is, 40 ohms, so that we arrive at the same result if instead of multiplying 5 by the conductivity 0·025, we divide it by the resistance 40, that is $\frac{5}{40}$ or $\frac{1}{8}$, or 0·125. So that as it is much more usual to speak about a circuit's resistance in ohms than its conductivity in mhos, the common expression of Ohm's law is that the current in a circuit is obtained in amperes by dividing the E.M.F. by the resistance. Thus, in a circuit of 100 volts and 1,000 ohms, the current would be $\frac{100}{1000}$, or 0·1 ampere, and by our previous rule the conductivity being $\frac{1}{1000}$, that is, 0·001 mho, the current would be $100 \times 0{\cdot}001$, or 0·1; of course, precisely the same result.

51. This unit current or ampere is that which transmits the unit quantity of electricity in one second. The unit of electric quantity is called the coulomb, and just as the unit flow of water through a pipe might be taken as that which allowed one gallon of water to pass any point in the pipe during one second of time, so the ampere is the strength of current, the rapidity of flow, which allows one coulomb to pass any point in the circuit during one second. So that if a constant current of one ampere has been flowing for 100 seconds in a circuit, then we know that 100 coulombs of electricity have passed any point in the circuit during that time. In the same way a steady current of five amperes flowing for one minute causes

Digitized by Google

a total transmission of 5 × 60, or 300 coulombs, and generally the quantity of electricity in coulombs transmitted by a constant current is the product of that current and the number of seconds it has been in flow.

52. For convenience in telegraphy a submultiple of the unit, the milliampere, is in very common use; it is the thousandth part of an ampere. To give an idea of what a milliampere practically is in telegraphy, it may be mentioned that on Morse land line circuits receiving becomes difficult to adjust and sustain when the received working current falls below one milliampere, which may be regarded as a minimum working current, while 5 milliamperes—that is, 0·005 amperes—is a good average working current. The current which enters the line at the sending end may be greater, and in the case of a long line in wet weather perhaps much greater than this; but the difference escapes by leakage at the insulators along the line, just as a quantity of water forced into a long pipe containing many small leaks would be much reduced in amount before its issue at the distant end.

53. The working current in a telegraph circuit whose insulation is good—so that the current escaping by leakage need not be considered—is easily found by Ohm's law. Suppose, for example, that we have an overhead land line 50 miles long, of 13ω resistances per mile, worked in the manner represented at Fig. 17—that is, on the open circuit principle, where no current passes through the line, except in actual signalling. The stations A and B are each provided with a Morse key, K, for sending the currents, a galvanoscope, G, of 30ω resistance, for observing that those currents duly pass, a Morse inkwriter or sounder, M, of 200ω resistance, and a battery, E, of 11 volts and 200ω total internal resistance. The levers of the keys are normally kept back by the spring *p* on the receiving contacts *r*. Under these

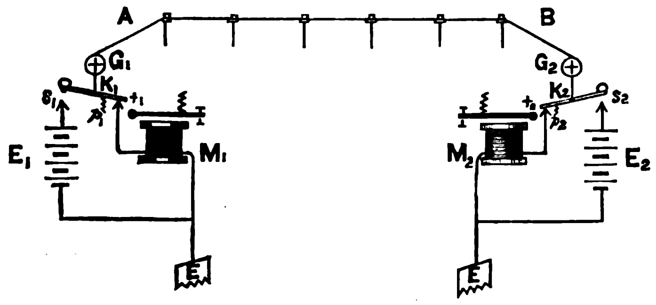

FIG. 17.

circumstances there is a complete circuit from A over the line returning by the earth and both receiving instruments, but in this circuit there is no battery. When A depresses his key, however, the circuit is completed no longer through the back stop and receiving instrument but through the front stop *s* and battery E, and a current from the latter therefore flows to line and actuates the galvanoscopes and instrument S. While A's key remains depressed we know from Ohm's law that the strength of current at any point in the circuit—there being assumed no leakage—will be the total E.M.F., namely 11, divided by the total resistance, which we can sum thus—

A's battery B	200ω
A's galvanoscope G........................	30ω
The line A B—	
Fifty miles at 13ω per mile	650ω
B's galvanoscope G........................	30ω
B's instrument M	200ω
The earth connections and the earth perhaps	1ω
Total	1,111ω

The current flowing will therefore be

$$\frac{11}{1111},$$

or $\frac{1}{101}$th part of one ampere—that is, 0·0091 ampere or 9·1 milliamperes.

(To be continued.)

A CURRENT INDICATOR FOR ARC-LIGHT CIRCUITS

We illustrate herewith a simple form of current indicator which is employed by the Anglo-American Brush Company. Fig. 1 shows the instrument set up, and Fig. 2 shows the various parts. From the latter figure it will be seen that the apparatus consists of a flat, square-shaped iron core, or armature, which is balanced on knife edges, projecting from the sides near the lower edge. It has therefore a tendency to fall on either side of the vertical. A long index needle is fixed at the top. This arrangement is placed within a solenoid

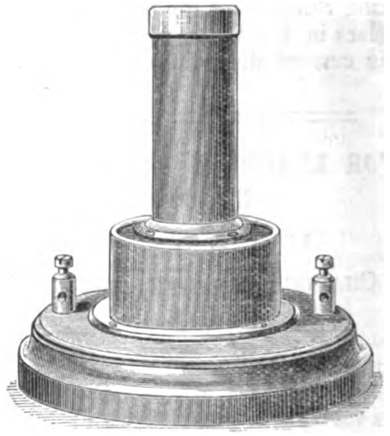

FIG. 1.

connected with the main circuit. On the passage of the current the armature tends to assume the vertical position, and this is opposed by the action of gravity. The index needle does not lie quite in the same plane as the prolongation of the core, hence it reaches the 10-ampere mark at the middle of the scale before the core itself attains a vertical position. By

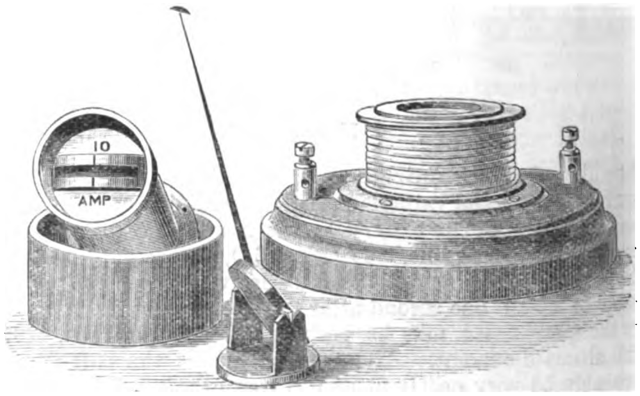

FIG. 2.

this arrangement the indicator is able to show an excess as well as a deficit from the normal current for which it is set.

THE MANUFACTURE OF INCANDESCENT LAMPS—AMYLOID CARBONS.

BY NELSON K. CHERRILL.

What was said last week tended to show that variation in the converting effect of the acid on the cotton thread would be found a fertile source of variation in the carbon produced; but I think we may go further than this, and may state almost with certainty that the process as carried out commercially contains in its very essence the germs of failure. If the action of the acid is cut short of complete conversion, the cotton may have still more of the characteristics of the fully converted article. It will still have the appearance of catgut,

Digitized by Google

and will cut easily in the dies used to reduce its diameter; but on examination under the microscope, or a strong lens, it will be seen still to retain evident traces of fibrous form; the original twist of the cotton will be often seen indicated by lines in the substance of the thread. If now such a sample of cotton be more fully converted, it will most likely be found to be quite cleared from the traces of fibrous form; but at the same time there are ten chances to one the cotton will be made too weak to draw through the dies, and it will consequently be condemned as rotten. In fact, to put the matter in a nutshell, if the acid treatment is prolonged to that point at which absolutely no fibrous traces remain, the cotton is generally too weak to draw well. The tendency of manufacture is therefore decidedly to use cotton too little rather than too much prepared. Now suppose that we carbonise a piece of quite unprepared cotton thread and examine the result in the microscope, we shall find a loose aggregation of carbon fibres having no cohesion one with another. If a piece of such a carbon filament be placed in a compressor (such as a tin box or lever compressorium) under the microscope, the various carbon fibres will be seen to move about amongst each other when the pressure of the covering glass is varied. When by the action of the acid the cotton fibres are, as it were, glued together, the resulting carbon presents under microscopic examination a like homogeneity of substance; but it is easy to see that if the action of the acid has been at all cut short of the most complete conversion there must always be a tendency for the inner fibres to be left loose in the burning, and hence I take it that in any thread which shows any sign of structure there is a serious liability for the lines which indicate structure to develop under firing into lines of imperfect homogeneity. It is impossible to judge of this point in the microscope, but the behaviour of the carbons when a current is passed through them may often be taken as an indication of their structural condition.

I shall have something to say on this point next week.

ELEMENTARY NOTE ON THE CALIBRATION OF GALVANOMETERS.

Galvanometers, or current-meters for large or small currents, which are not constructed on the tangent principle require to have their scales graduated in divisions proportional to the currents passed through them; or, if their scales are marked out in degrees of arc, a number of readings must be taken with currents of known ratios, whose values, together with the corresponding deflections of the galvanometer, are plotted on a curve for reference when currents are measured on the instrument.

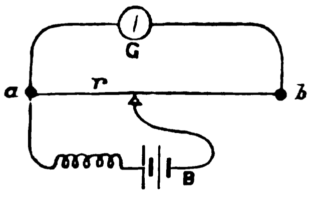

Fig. 1.

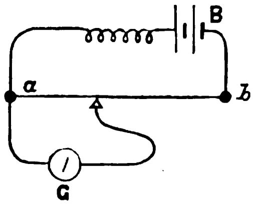

Fig. 2.

If a galvanometer (such as a tangent) or ammeter, whose proportionality to the current is known, is available, it may be connected in series with the ammeters to be tested, and *any* currents passed through for comparison.

Prof. Grassi, in a paper read before the Naples Academy in June last, proposes some modifications of Nacarri's method for the graduation of a galvanometer in divisions proportional to the current by the simple movement of a sliding contact on a stretched wire, the distances moved over being proportional to the currents through the instrument.

The arrangement in Fig. 1 would be used for a low-resistance galvanometer.

The current through the galvanometer with the pointer or sliding contact D in any position on the wire A B will be

$$\frac{E r}{r_1 (R+G)+r(R+G-r)} \quad . \quad . \quad . \quad . \quad (1)$$

where

r_1 = resistance of battery and any resistance in battery circuit.
E = battery E.M.F.
R = resistance of wire A B.
G = resistance of galvanometer.
r = resistance of portion of wire between A and sliding contact D.

The denominator comprises two terms, the first of which is constant and the second variable.

If, now, the resistance r_1 is made very large in comparison to G and R, the variation in the value of the denominator —while D moves the whole length of A B—is very small compared to the actual value of the denominator. We may therefore take the latter as constant, and if the E.M.F. is constant, the currents through G vary as the distances of the sliding contact from A.

It is evident that the greatest variation in the denominator when G = R is R^2, and when G has any other value the maximum variation is $\frac{(R+G)^2}{4}$. This being made very small compared to r_1 (R + G) by a resistance inserted in the battery circuit, the arrangement is suitable for the graduation of low-resistance galvanometers.

Reversing the positions of battery and galvanometer as in Fig. 2, we have an arrangement for graduating high-resistance galvanometers.

The current through G will be

$$\frac{E r}{G(R+r_1)+r(R+r_1-r)} \quad . \quad . \quad . \quad . \quad (2)$$

Comparing this with (1) we see that G and r_1 have changed places, and therefore when $r_1 = R$ the maximum variation of denominator is R^2 and when r_1 is any other value the variation is $\frac{(R+r_1)^2}{4}$ This must be small compared to $G(R+r_1)$ which is effected by employing the method with a high-resistance galvanometer, and low-resistance battery.

Prof. Grassi improves the accuracy of the method for cases where the resistances of the galvanometer and battery more nearly approach each other by employing two slide wires, A B, of resistance R, and M N of resistance n R (Fig. 3), these two being connected together through a travelling contact, D. The current through galvanometer for any position of contact D is

$$\frac{E r}{(R+G)(r_1+nR) + (R+G)(1-n)r-r^2} \quad . \quad (3)$$

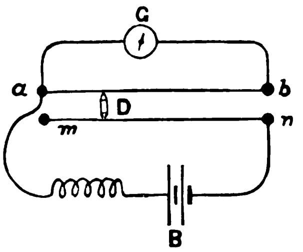

Fig 3.

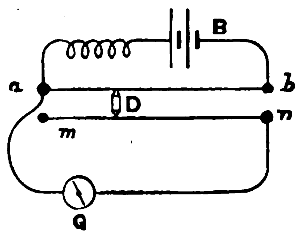

Fig. 4.

Calling this denominator V, we have its value changed to V_1 when the pointer is at the end B

when $$V_1 = (R+G)r_1 + RG \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and to V_0 when the pointer is at A

when $$V_0 = (R+G)\ (r_1+nR)$$

and the greatest possible value of the denoninator would be

$$V_2 = (R+G)(r_1+nR) + \frac{(R+G)^2}{4}(1-n)^2.$$

Digitized by Google

It is found that the minimum variation is attained when $V_0 = V_1$, and therefore $n = \frac{G}{R+G}$, with which values the variation is reduced to $\frac{R^2}{4}$, and this is quite independent of the resistances of the galvanometer and battery. If a low resistance galvanometer is used n becomes very small and nR negligible, and we revert to the single wire as in Fig 1.

Similarly if the battery and galvanometer are reversed (Fig. 4) the current through G is

$$\frac{E\,r}{(R+r_1)\,(G+n\,R)+(R+r_1)\,(1-n)\,r-r^2} \quad . \quad (5)$$

and the maximum variation in the denominator becomes $\frac{R^2}{4}$ by making $n = \frac{r_1}{R+r_1}$.

We see also that by employing a low-resistance battery nR becomes negligible, and we revert to the single wire, as in Fig. 2.

Under the above conditions the currents passing through the galvanometer to be graduated, or whose scale divisions require to be checked, are proportional to r, viz., to the distance of the sliding contact from the point A, and this it is seen can be done without knowing accurately any of the resistances in the circuit.

ELECTRIC OSMOSE AND ELECTRO-CAPILLARY ACTION.*

Assuming with Clausius that in a case of electrolysis taking place in a liquid between, say, platinum electrodes, a polaric *bias* is put upon the otherwise chaotic evolutions of the molecules of the electrolyte by the E.M.F. of the current, it seems not unlikely that if the + and − ions be of unequal mass and the forces urging them in contrary directions be equal, *more work will be done upon the lighter radicles* than upon the heavier ones at each semi-revolution of the molecules of the Grotthus chains (after each liberation of ions at the electrode surfaces), owing to the difference of inertia; and that the liquid will in consequence be urged towards that electrode towards which the lighter radicle is moving; also, that if a friction be introduced by placing a porous diaphragm or a series of porous diaphragms across the liquid, the back flow of the liquid *within the pores will* be retarded, and a difference of level on the two sides of each septum limited only by the strength of the current and the efficiency and thickness of the septum will be produced.

I have been led to think that this action may account for the phénomena of electric osmose and allied effects by the following considerations:—

(1) Electric osmose is most marked in electrolytes whose molecules are of great relative unwieldiness and disparity of weight between their + and − components, as in the case of organic compounds.

(2) The ion moving towards the cathode (H in the majority of cases) is generally the lighter of the two ions, which accords with the rise of liquid around the cathode in general. In cases which would seem to contradict this hypothesis it may be that the elements *visibly* liberated at the anode are not the only ones which accompany the − ions on their journey and add to their inertia.

(3) That by reason of more work being done on the + ions than on the others the cathode is more strongly bombarded than is the anode by the elements liberated against it, so that if either electrode be varnished on one face and floated, or made with vanes like Crookes's radiometer, or hung in the liquid, pendulum fashion, it will move to or fro with different force to the other in like circumstances, as in the capillary electrometer of Dewar.

(4) That the facts are not less consistent with the rather-more-difficult-to-grasp view that the active molecules of the Grotthus chains, in performing their semi-revolutions from the positions in which they are formed at every change of partners, following the liberation of each pair of complemental ions at the ends of the chains, swing round their centres of mass; and even if their centres of bulk be coincident with their centres of mass it may be that the friction they exert against contiguous molecules in turning "right about face" is greater or less for one direction of reversal than for the other, owing to the different nature of the two halves of each molecule. Wherefore the whole of the active molecules are impelled one way, and all the inactive molecules the other, with equal momentum but not necessarily equal volumes.

(5) That if the centres of bulk of the active molecules be displaced, their friction against neighbouring molecules will, by their being disseminated in infinite number throughout the liquid, urge it as a whole in one direction just as a net of fine mesh would do.

(6) The apparent disagreement between this hypothesis and the fact that—at least, when the electrodes are fixed—the + and − ions each undergo equal displacement in opposite directions, as evidenced by their being given off in equivalent quantities at the electrodes, will be seen to be *only apparent* when it is remembered that every time a + and − element is liberated at the ends of the Grotthus chains, those chains are left one molecule too short, and that there is an abundance of molecules ready to fall into file all along the line, so that more will therefore fall in at that end from which the active molecules tend to be displaced. R. SNOWDON.

Staveley Ironworks, Chesterfield.

* A communication to the Electrolysis Committee of the British Association, Manchester, 1887.

OBSERVATIONS ON ATMOSPHERIC ELECTRICITY.*

BY PROF. L. WEBER.

I will try to give a short report of some experiments I have made during the last year in regard to atmospheric electricity. It was formerly uncertain whether the electrostatic potential would increase by rising from the surface of the earth to more elevated regions of the atmosphere or not, and also whether the potential in a normal—that is, cloudless—state of the atmosphere was always positive or sometimes negative. Sir Wm. Thomson found by exact methods of measuring that the increase of the potential with elevation is very important, and values about 100 volts per metre. That fact is proved by many other observers, especially lately by Mr. F. Exner at Vienna, who found an increase of 60 to 600 volts per metre. These observations were made by means of an electrometer. In respect of many inconveniences which are connected with the use of an electrometer, I have tried the measurements with a very sensitive galvanometer. In this case it is necessary to apply a separating air-exhaust apparatus, for example, flame, or a system of points at the upper end of the conductor, which is elevated in the atmosphere. In order to get a constant apparatus I have used 400 of the finest needles inserted in a metallic ribbon. This system I have raised in the air by means of a captive balloon, or by a kite, which was attached to a conductor of twine or to a twisted line of the finest steel wire. In this way I have attained a height of 100 to 300 metres. When the lower end of the kite line was communicating with the galvanometer whose other terminal was in contact with the earth, a current passed through the galvanometer. For determining the strength of this current I proposed to call a micro-ampere the 10^{-9} part of an ampere. At the height of about 100 metres in the average the current begins to be regular, and increases at the height of 300 metres to 4,000 or 5,000 of these units. The increase is very regular, and seems to be a linear function of the height. I have, nevertheless, found the smallest quantities of dust contained in the atmosphere or the lightest veil of cirrus disturbed the measurement very materially, and generally made the potential lower. In negative experiments of this nature I have made at Breslau, at the Sohneekoppe, and at the "Reisengebirge," especially at the last station, an

* Abstract of a paper read before the British Association Meeting at Manchester, Sept., 1887.

Digitized by Google

increase of potential was observed, not only by reason of the perpendicular height, but also by reaching such regions of the atmosphere as were situated horizontally to about 200 metres from the utmost steep of the same mountain, Sohneekoppe. Therefore it must, according to Mr. Exner, be assumed that the surface of the air presents a surface of equal potential, and that the falling surfaces of high potential were stretched parallel over the plane contours of the air, and more thinly or narrow lying over all the elevated points, as for example, mountains, church towers, &c. On the basis of these facts I think it easy to explain the electricity of thunderstorm clouds; in fact every cloud, or every part of a cloud, may be considered as a leading conductor, such clouds as have for the most part perpendicular height. After being induced the change results by supposing the conduction of electricity either from the upper or from the lower side, according to greater or smaller speed of the air in the height. In the first case the clouds will be charged positive, in the other negative. I am inclined, therefore, to state that the electricity of thunderstorm clouds must be considered as a special but disturbed case of the normal electric state of the atmosphere, and that all attempts to explain thunderstorm electricity must be based on the study of the normal electric state of the atmosphere.

A THOMSON BRIDGE FOR THE MEASUREMENT OF SMALL RESISTANCES.*

Messrs. Siemens and Halske have in process of manufacture a bridge of the pattern devised by Sir William Thomson, and

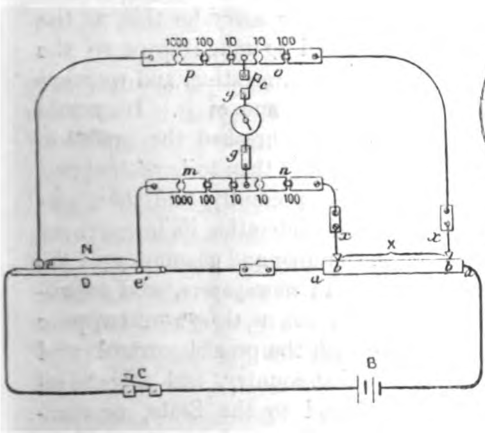

Fig. 1.

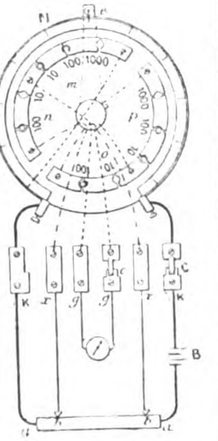

Fig. 3.

especially designed for the rapid and accurate measurement of small resistances. It will be remembered that the chief value of this arrangement lies in the fact that the influence of the spurious resistances due to the contacts with conductor of low resistance is entirely eliminated. The conductor whose resistance is to be measured is balanced against an arm of the bridge whose resistance is of the same order; but the resistance of the remaining branches of the circuit (which are in series with one or other of the four *contacts* of the low resistance conductors) are of a higher order, and hence these contact resistances are negligible. The bridge in question is adapted to the measurement of resistances varying from 0·1 ohm to 0·000,001 ohm.

Fig. 1 shows the diagram of the connections. The principal circuit is made up of the battery B, the key C, a conductor, D, and the resistance X, whose value is to be determined. Two points, *e e′*, in the conductor D, and two points, *b b*, at or near the extremities of the conductor X, are respectively connected with a pair of resistance boxes, as shown. The galvanometer bridges the circuit between the two arms of the resistance boxes.

If the total resistance in the branch m = that of branch n, and likewise $o = p$, there will be no current in the galvanometer, and then $X = N$,

* From the *Elektrotechnische Zeitschrift.*

where N equals the resistance of conductor D between the points $e\ e^1$.

This resistance N can be varied within limits by sliding one of the contact pieces e. In this way resistances can be measured whose value is at the maximum not greater than that of N. If the resistances of N and X are very different, the resistances m, n, o, p are adjusted so that

$$\frac{n}{m} = \frac{o}{p}.$$

We have then $X = N\,\frac{o}{p}$, and the value of X as read by the slider has simply to be multiplied by a decimal constant.

In the instrument of MM. Siemens and Halske, which is shown in Fig. 2, the conductor D consists of a circle of palladium, which is fixed upon a wooden block. The circle is finely divided at the margin. The sliding contact e is made by a movable arm pivoted at the centre of this circle, and provided with a vernier for accurate reading. The contact e' is fixed.

The plug contacts of the resistances m, n, o, p are arranged around the same circle. The terminals for the remaining connections are placed upon the front of the base board, and the manner of joining up will easily be seen on comparing Fig. 3 with Fig. 1, in which the same lettering is employed. Flexible wires are connected to the points $x\ x$ for joining up the resistance to be measured.

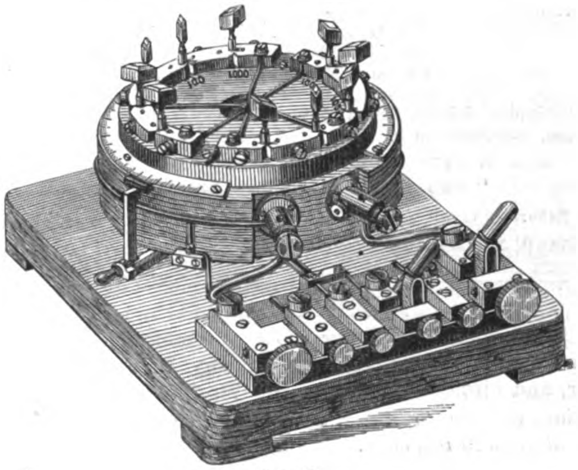

Fig. 2.

As an example of the employment of the apparatus, suppose that $n = 10$, $m = 1{,}000$, and $N = 0{\cdot}0051$, we should then have

$$X = 0{\cdot}0051 \times \frac{1}{1000} = 0{\cdot}000051 \text{ ohm.}$$

This new model of the Thomson bridge is a very practical piece of apparatus, and will unquestionably be extremely useful in facilitating the measurements of minute resistances.

MEETINGS OF SCIENTIFIC SOCIETIES.

(Week ending Thursday, 5th January.)

SATURDAY, December 31st.

Royal Institution.

3 p.m. The Third of a Series of Six Lectures (adapted to a Juvenile Auditory) on Astronomy. By Sir Robert Stawell Ball, LL D., F.R S.

MONDAY, January 2nd.

Society of Engineers.

Meeting.

WEDNESDAY, January 4th.

Society of Arts.

Juvenile Lecture I. "The Application of Electricity to Lighting and Working." By Mr. W. H. Preece, F.R.S.

*** Particulars of meetings to be held or papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

The DIRECTORY *is an excellent advertising medium.*

The 1888 Edition will be ready next week.

NOW READY.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

THE TELEGRAPH IN AMERICA.

Our latest intelligence from the United States seems to point to the abandonment, for the present at all events, of the movement for establishing a telegraph system under the control of the Government. We are rather sorry for this, as the discussion which has recently occupied so much space in the American papers was beginning to be interesting, and we were growing curious to see what would come of it. It would have been more satisfactory to have thrashed the question out thoroughly while they were about it than to have dropped it suddenly, only to take it up again presently, and then perhaps settle it off-hand without the consideration its importance demands. If we may judge by the number and unanimity of the opinions extracted from the American newspapers, and reproduced in the technical journals which reach us, there would appear to be widespread dissatisfaction with the present control and management of the telegraphs in that country, and a general desire to have them either transferred to the State, or compelled to give a better service by its active competition. "Never," writes one of these authorities, "were the people more in favour of a Governmental control of the telegraph;" and most of the papers at the commencement of the month spoke in the same strain. Subsequently, however, there came the President's message, proposing the reduction of import duties; and in the excitement caused by this announcement the other question has been temporarily set aside.

If we are to take this as the inauguration of a settled change of policy, the surplus revenue going to reduce import duties more and more every year, then probably the question of buying or creating a Government telegraph system will be postponed indefinitely. But the principles of Free Trade have not made such headway in the States as to warrant this conclusion; and it seems to us more than probable that in the present condition of political parties the advantages of possessing a national telegraph system will outweigh those of enjoying the unrestricted importation of foreign commodities. America is unique in having a surplus revenue which she does not exactly know what to do with; and unless she is now about to make a departure in her fiscal system differing altogether from her established traditions, that surplus will again very soon be available for reforming the telegraph service of the country, and will, we imagine, be devoted to that purpose. Perhaps

Digitized by Google

the delay may be of some advantage, for although Bills appear to have been prepared for the forthcoming Congress, the country is not yet entirely agreed as to the form which the measure should take—whether for the buying up of the existing telegraphs, or the institution of an independent system under the control of the Government. Until this preliminary point is settled, obviously no progress can be made in the Legislature; and it is a point of such immense importance that no time can be considered wasted which is devoted to discussing it thoroughly.

The question which our friends in America will have to determine before they spend a single cent on this undertaking is, whether they are going to enter on the business of telegraphy as monopolists or as competitors? If the former, the operation will be a gigantic one; but it is one that money will pay for, and is by no means beyond the resources of a country that collects more taxes than it can honestly spend. If the latter, then the question arises, or would very soon arise when the competition began, is the country so rich as to afford to squander money year after year on a war of rates with its private competitors, increasing the telegraphic facilities beyond all reasonable requirements, and removing further and further away the possibilities of absorbing at a reasonable figure the whole system into Government hands? That the existing companies could be brought to their knees by a simple threat of Government opposition is incredible; and to confront the companies on even terms the Government must establish a system equal in magnitude to theirs, when one or the other would be superfluous. A purchase under such conditions would be inevitable, but would be waste of money at the best. We say inevitable, because it would be the policy of the private companies to hold on and fight the battle until the State became sick of taxing the public all round in order to carry on a ruinous business merely for the benefit of the senders of telegrams. Private property is more secure in the United States even than with us, its sanctity being formally recognised in the Constitution. Confiscation, or compulsory purchase at marine-store-dealers' valuation—which is sometimes talked about in this country—is therefore out of the question; and it follows that by postponing the day of purchase the price at which it can be effected will be proportionately enhanced.

Notwithstanding these self-evident considerations, an influential body of public opinion in the States is at present favourable to competition rather than purchase. The reason is not far to seek. So obnoxious has the monopoly of the principal telegraph company become, that to crush it by competition is regarded as an act of justice, while to buy it up seems like a piece of extravagant magnanimity. And this feeling is intensified by the personality of the one man who largely owns and wholly controls the existing monopoly. One of the chief demerits of personal government, whether in politics or trade, is that it is provocative of envy, hatred and all uncharitableness. Porbably neither Mr. JAY GOULD nor the Western Union Telegraph is guilty of a tithe of the enormities laid to their charge; but even were it otherwise, the fault would rest very largely with the Government which has permitted the amalgamation of the c ompanies, the creation of a vast monopoly, and the domination of the great capitalist whom the American press anathematises as "that man." Speaking impartially on this point, we venture to observe that the Americans ought to be thankful that these evils can at any time be easily set right; and that the inferiority of the Government in those qualities of boldness, enterprise, and foresight which the private companies have displayed may be condoned by prompt decision and cash down. We ourselves were behind the rest of Europe in placing the telegraphs under Government control; but when we did so we paid for our backwardness. And this, we suspect, is what the United States Government would have to do in like circumstances.

On the question whether or not the United States should follow the example of Europe in assuming the control of the national telegraphs we offer no decisive opinion. All that we confidently assert is that to be effectual the control must be complete. The Government must have a monopoly, for the working of which it will be responsible to the country. It will never do to permit two or more identical systems for the public service with public control over only one of them. Our own experience in relation to the telephone ought to be a warning to America. Notwithstanding the Government monopoly a vast telephone system has been allowed to grow up outside of it, and, except for the payment of a small royalty, independent of it. The telephone is rapidly developing a business which threatens to seriously invade, if it does not exactly rival, that of the Postal Telegraphs. This is serious enough in its financial aspect; but in the interest of the public it is even still more serious. Already there is much dissatisfaction because the telephone service is not what it ought to be. Being in private hands it is worked exclusively for profit; and the Government is blamed, first for taking the royalty, next for not creating a more perfect system of its own. The fact is, the Government cannot afford either to dispense with the one or to competitively run the other. Meanwhile the companies do what seemeth to them best, and the country complains that this important branch of telegraphy is not covered by the thirteen millions sterling which was paid for establishing the Government telegraphs eighteen years ago. How this difficulty will be got over it is hard to say, but certainly not by the competition of the Government; far more probably by its acquisition of the rights of the existing telephone companies.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(Continued from page 157.)

Chlorides of Iron and Magnesium.—To prepare this bath a solution of acid protochloride of iron was first neutralised with carbonate of magnesia and then filtered. The clear liquor was then electrolysed with the current from three small Daniell cells, in series, when a dark bluish-grey film was immediately obtained upon a brass cathode. Two cells were next tried, when, as before, the deposit took place instantaneously; the solution was now diluted and a fresh plate immersed. The deposition being still too quick, however, more water was added to the bath, when the character of the deposit improved. The current from a single cell was next tried, with still further advantage, since the film now became whiter and more bright. With the single cell there was but little evolution of gas, but in a short time the liquid became murky. A moderate addition of a solution of chloride of magnesium was now made, and the solution well stirred, when it at once became light and clear. A freshly-prepared brass plate was then immersed, which soon became coated with a film of iron of a good white colour and very adherent. The deposition being still rather more speedy than was desirable for a good reguline and tenacious deposit, the anode surface was reduced to about equal that of the negative electrode, when the deposit took place more gradually, and the character of the film greatly improved. There was, however, considerably more gas eliminated after the addition of the magnesium salt, and the hydrogen bubbles had a tendency to rest upon the plate.

Chlorides of Iron and Sodium.—A moderately strong solution of the protochloride of iron was first made, and to this was gradually added a strong solution of carbonate of soda, until the liquid was neutral to litmus paper. With the current from three Daniells, and large anode surface, a partial film of iron slowly formed on the brass cathode, and at the same time a white gelatinous deposit appeared on the plate, which was ejected from the surface by the hydrogen (which was very copious), and finally deposited at the bottom of the vessel. A few drops of hydrochloric acid were now added to the liquid, when the solution became clear; the anode surface was also increased, when a bright film of iron slowly formed upon the plate. The solution was next diluted with about double its volume of water, and a small quantity of common salt added and dissolved in the liquid, when the deposition immediately improved in every way, being not only more rapid, but the film became perfectly bright, and of a brilliantly white colour. It was found necessary now, however, to reduce the anode surface considerably, little more than half that of the cathode being sufficient. It was next determined to reduce the number of cells, 1 and 2 cells respectively being tried, but the most suitable current was obtained from the latter number of cells in series, and equal electrode surface, with which a fine white and remarkably bright and adherent film was obtained at a fair rate of deposit. Although this solution of the mixed salts is capable of yielding very favourable results, it is scarcely one that could be recommended for practical working, inasmuch as it might be somewhat uncertain in its performance as an electrolyte, unless the current and anode surface were regulated, as we have seen, to a degree of nicety that is scarcely so necessary with some of the solutions described in the former papers of this series.

Nitrates of Iron and Potassa.—This bath was prepared by adding to a solution of protonitrate of iron one of nitrate of potassa, the compound solution being of moderate strength. The current from a single Daniell cell was first tried, when a dull, opaque film of a non-metallic character—probably a subsalt of iron—was obtained upon the cathode. Two cells were next tried, with similar results. A third cell was then connected in series, when, after a short immersion of a brass cathode, a dark green salt formed upon its surface, and in about two minutes after accumulated on the plate as a green spongy mass, finally falling off the surface and depositing at the bottom of the vessel. This green salt, when exposed to the air, oxidised with great rapidity, forming a rusty compound of somewhat brighter colour than ordinary rust of iron. No metallic deposit of iron could be obtained from this bath with any modification that suggested itself, either in strength of current or density of the liquid, so the experiment was abandoned. It should be mentioned, however, that the dark green salt referred to sometimes formed an adherent film—apparently transparent—which could only be detached from the plate by force, while the remainder of the same material, which formed the upper layer of the deposit, came away from the plate spontaneously, or was easily removed by wiping it off with the finger. I may mention the fact that I have frequently met with the same dark green, semi-adherent substance when electrolysing some of the persalts of iron.

Iodide of Iron.—This salt was first prepared by digesting fine iron wire in warm water, to which was added a quantity of iodine, the containing vessel being repeatedly shaken at intervals of an hour or so, and then allowed to repose until the following day, by which time the iodine had disappeared, and the solution was ready for use. The liquid, which had a greenish tint, was moderately diluted with water, and then electrolysed with two Daniell cells, when a film, of a blued steel colour, was promptly obtained upon a brass cathode. A single cell was next tried, when the deposit was still very rapid, of a dark colour and dull, but very adherent. After a time the solution became turbid from decomposition, and the experiment was then discontinued.

Ferrocyanide of Potassium and Iron (Soluble Prussian Blue).—A solution of this double salt was formed by adding a solution of perchloride of iron to one of ferro cyanide of potassium, the latter being in excess. The precipitate of Prussian blue thus obtained was, after filtering, dissolved in water, and the resulting liquid then gently warmed and electrolysed with a current from one, up to five, Daniells, but no deposit of iron could be obtained upon a brass cathode. The liquid was then heated to about 120deg. F., but with no better result, so the experiment was pursued no farther.

Tannate of Iron.—This electrolyte was prepared by cautiously adding a solution of tannic acid to one of perchloride of iron, avoiding an excess of the former. The black liquid thus obtained was then heated and electrolysed with the current from four Daniells, when a slight metallic film was received upon a brass plate, but only in patches, while other parts of the plate became coated with a dark brown, tolerably adherent non-metallic film. A good deal of gas was liberated at both poles, which rested on the surface of the liquid in very large bubbles, and when the cathode was lifted out of the bath these came away with it and remained for some time upon its surface without breaking, a peculiarity before observed in respect of the electrolysis of the pernitrate of iron solution. The bath was now heated, but with little or no advantage, since nothing but a trifling deposit of iron, in parts of the plate only, could be obtained, while a gelatinous deposit formed upon the plate, indicating that the solution was gradually decomposing.

Gallate of Iron.—A solution of gallic acid was gradually added to one of perchloride of iron, and the blue black liquid thus obtained was electrolysed with the current from four Daniells. The results were of a precisely similar character to the preceding, except that there was no actual film of metallic iron; the only deposit obtainable was a brown non-metallic film.

Potassio-oxalate of Iron.—A solution of this salt was prepared by Graham's method, namely, by dissolving hydrated peroxide of iron in a solution of binoxalate of potassa, a pale green solution being obtained, which was first electrolysed with a single Daniell, when an opaque, white and firmly adherent insoluble salt was deposited upon the cathode. Three cells were then tried, when a tardy deposit of metallic iron, of fairly good colour, appeared on the surface of a freshly prepared plate. The liquid was afterwards heated, and it this state it yielded a very white film of iron, which was firmly adherent. It is a singular fact that when the plate was first put into the bath after it had been heated, that the same opaque film, before noticed, at once appeared on its surface, but when the plate was allowed to rest undisturbed for a few minutes, this film disappeared, and the metallic deposit then occupied its place.

Pertartrate of Iron.—A bath was prepared from this salt by digesting recently precipitated and moist hydrated peroxide of iron in a boiling solution of tartaric acid. The resulting liquid, which, after filtration, was of a bright yellow colour, was diluted, and then tried with a current from four Daniells, when there was a brisk liberation of hydrogen, but no deposit of metal appeared on the cathode. The strength of the current was then gradually reduced, until finally a single cell was tried, but without any result. The liquid was then heated, and the experiment repeated with the same variations of current strength, but only a slight film of iron could be obtained with the warm solution, four cells being used, by briskly moving the cathode about in the bath; when stationary, no deposit whatever could be obtained. It was next determined to try the effect of dilution, as I had previously found that metallic deposits could be obtained from highly attenuated solutions of persalts of iron, which were impossible with stronger liquids. Water was now added until the bath had become diluted to about ten times its original volume. With four Daniells and increased anode surface, a bright film of metallic iron soon appeared upon a brass plate, except at the lower corners, where there was no deposit. Farther additions of water were afterwards given, a fresh plate being immersed after each addition, until the solution had become weakened to the extent of about twenty times its original bulk, when even in this very dilute condition films of metallic iron were obtained. The results of this experiment

clearly show that under certain conditions of the electrolyte—extreme dilution, apparently, being the most essential condition—solutions of iron persalts will give up their metal by electrolysis; and if this has hitherto been considered unattainable it must be evident that such necessary conditions have not been fulfilled by those who have experimented with these salts.

(To be continued.)

REVIEWS.

Management of Accumulators and Private Electric Light Installations: A Practical Handbook. By Sir DAVID SALOMONS, Bart., M.A., A.I.C.E., M.S.T.E. Third Edition, revised and enlarged. (London: Whittaker and Co.)

The third edition of Sir David Salomons' now well-known handbook is, to all intents and purposes, a new work. The number of pages in this edition has been extended from a scanty 31 to no less than 140. The style and get up of the book have at the same time been much improved, and the text is now illustrated with numerous engravings. Many readers will, however, regret to learn that the portrait of the author, which formerly graced the frontispiece, has been omitted from this edition.

The substance of the additional matter is clearly indicated by the second clause of the title, and consists chiefly of advice and instructions on the management of engines and dynamo machines. The instructions are given in the same careful and practical manner which characterises the earlier hints on the management of accumulators. The author has made it his business—as it is evidently also his pleasure—to make trials of a large number of appliances with a view to the discovery of the best possible combination of apparatus for employment in a private installation of electric light.

Sir David Salomons has always been an advocate of the employment of automatic methods of working wherever such methods can possibly be introduced with advantage, and although this must necessarily add to the original cost of the installation, yet provided that the apparatus can themselves be relied upon, there is no question as to the superiority of this style of installation in point of convenience, safety, and reliability. By the kind permission of the author we are enabled to reproduce the detailed table of estimates (pp. 138-139), giving the relative expenditure for installations of various types and sizes. (*See* preceding column).

In a fourth edition, which will probably be called for at an early date, care should, however, be taken to remove some minor blemishes which now disfigure the work, and which should for the most part have been discovered by the publishers' proof-reader. Such, for instance, as occur on pp. 72 and 73, where there are several drawings adorned with letters which are nowhere referred to in the text. Again, a few pages further on, we read with surprise that "if the engine-house is made totally inflammable there is no necessity to insure against fire."

A Scheme for Local, County, and National Government. By J. CLEGG, M.R.C.S L. (Bournemouth: Mate and Sons.)

As the question of local government reform is ripening for decision, and as electric lighting development is concerned with the form which the scheme will finally take, this little pamphlet will be found useful. The author seems to have had a large experience in the matters on which he treats.

SPECIFIC INDUCTIVE CAPACITY.*

BY J. HOPKINSON, M.A., D.SC., F.R.S.

The experiments which are the subject of the present communication were originally undertaken with a view to ascertain whether or not various methods of determination would give the same values to the specific inductive capacities of dielectrics. The programme was subsequently narrowed, as there appeared to be no evidence of serious discrepancy by existing methods.

* Paper read before the Royal Society, Nov. 17th, 1887.

Digitized by Google

In most cases the method of experiment has been a modification of the method proposed by Prof. Maxwell, and employed by Mr. Gordon. The only vice in Mr. Gordon's employment of that method was that plates of dielectrics of dimensions comparable with their thickness were regarded as of infinite area, and thus an error of unexpectedly great magnitude was introduced.

For determining the capacity of liquids, the apparatus consisted of a combination of four air condensers, with a fifth for containing the liquid, arranged as in a Wheatstone bridge, Fig. 1. Two, E, F, were of determinate and approximately equal capacity, the other two, J, I, were adjustable slides, the capacity of either condenser being varied by the sliding part. The outer coatings of the condensers E, F, were connected to the case of the quadrant electrometer, and to one pole of the induction coil; the outer coatings of the other pair, J, I, were connected to the needle of the electrometer and to the other pole of the induction coil. The inner coatings of the condensers J, F, were connected to one quadrant, and I, E, to the other quadrant of the electrometer. The slide of one or both condensers J, I, was adjusted till upon exciting the induction coil no deflection was observed on the electrometer. A dummy was provided with the fluid condenser, as in my former experiments, to represent the necessary supports and connections outside of the liquid. Let, now, x be the reading of the sliding

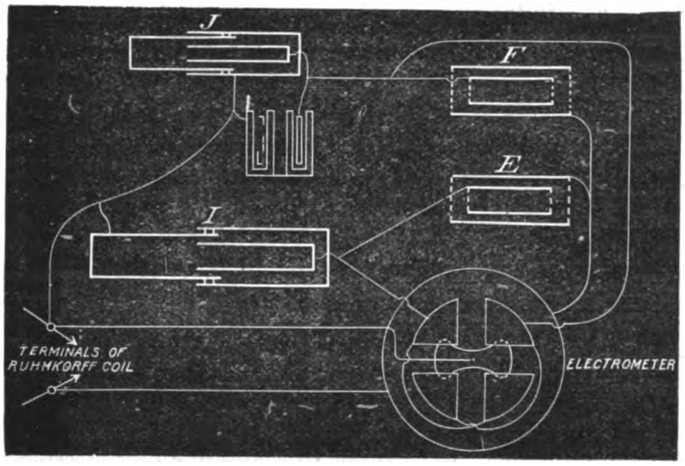

Fig. 1.

condenser when no condenser for fluid is introduced, and a balance is obtained. Let y be its reading when the condenser is introduced fitted with its dummy, z when the full condenser is charged with air. Let z_1 be the reading when the condenser charged with fluid is introduced, then will K, the specific inductive capacity of the liquid, be equal to $(y - z_1)/(y - z)$.

Three fluid condensers were employed. One was the same as in my former experiments;* another was a smaller one of the same type arranged simply to contain a smaller quantity of fluid; the third was of a different type designed to prove that by no chance did anything depend on the type of condenser. This done it was laid aside as more complicated in use.

To determine the capacity of a solid, the guard ring condenser of my previous experiments† was used. Advantage was taken of the fact that at the time when there is a balance the potentials of the interiors of all the condensers are the same. Let the ring O of the guard ring condenser be in all cases connected to J, let the inner plate of the guard ring be connected to J, as in Fig. 2, and let a balance be obtained. Let the inner plate be now transferred to I, as in Fig. 3, and again let a balance be obtained; the difference of the two readings on the slide represents on a certain arbitrary scale the capacity of the guard-ring condenser at its then distance.

In some cases it was necessary to adjust both condensers to obtain a balance; then the value of a movement of the scale of one condenser in terms of the other was known from previous experiment. In some cases it was found most convenient to introduce a condenser of capacity known in divisions of the scale of the sliding condenser coupled as forming part of the condenser J. The old method of adding the opposite charges of two condensers, then connecting to the electrometer and adjusting until the electrometer remained undisturbed, was occasionally used as a check; it was found to give substantially the same results as the method here described when the substance insulated sufficiently well to give any results at all.

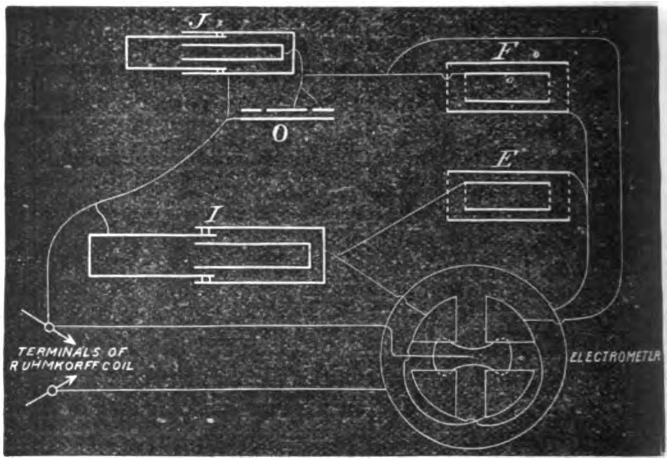

Fig. 2.

Colza Oil.—This oil had been found not to insulate sufficiently well for a test by the method of my former paper. Most samples, however, were sufficiently insulating for the present method. Seven samples were tested with the following mean results:—

No. 1. This oil was kindly procured direct from Italy for these experiments by Mr. J. C. Field, and was tested as supplied to me—

$$K = 3{\cdot}10.$$

No. 2 was purchased from Mr. Sugg, and tested as supplied—

$$K = 3{\cdot}14.$$

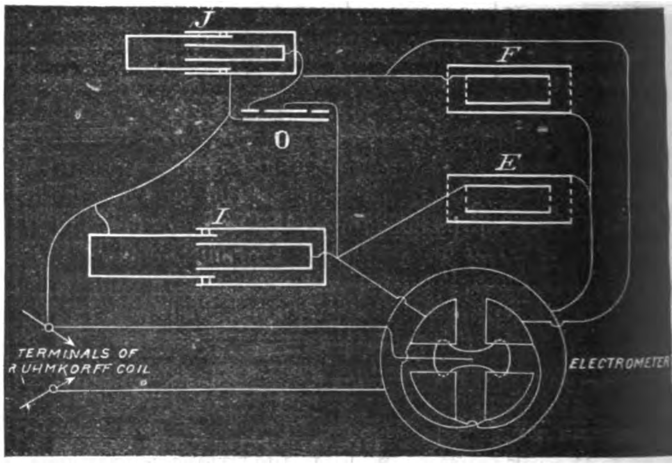

Fig. 3.

No. 3 was purchased from Messrs. Griffin, and was dried over anhydrous copper sulphate—

$$K = 3{\cdot}23.$$

No. 4 was refined rape oil purchased from Messrs. Pinchin and Johnson, and tested as supplied—

$$K = 3{\cdot}08.$$

No. 5 was the same oil as No. 4, but dried over anhydrous copper sulphate—

$$K = 3{\cdot}07.$$

No. 6 was unrefined rape purchased from Messrs. Pinchin and Johnson, and tested as supplied, the insulation being bad,

* *Phil. Trans.*, 1881, Part II. † *Phil. Trans.*, 1878, Part I.

Digitized by Google

but still not so bad as to prevent testing—

$K = 3{\cdot}12$.

No. 7. The same oil dried over sulphate of copper—

$K = 3{\cdot}09$.

Omitting No. 3, which I cannot, indeed, say of my own knowledge was pure colza oil at all, we may I think, conclude that the specific inductive capacity of colza oil lies between 3·07 and 3·14.

Prof. Quincke gives 2·385 for the method of attraction between the plates of a condenser, 3·296 for the method of lateral compression of a bubble of gas. Palaz* gives 3·027.

Olive Oil.—The sample was supplied me by Mr. J. C. Field—

$K = 3{\cdot}15$.

The result I obtained by another method in 1880 was 3·16. Two other oils were supplied to me by Mr. J. C. Field.

Arachide.—$K = 3{\cdot}17$.

Sesame.—$K = 3{\cdot}17$.

A commercial sample of *raw linseed oil* gave $K = 3{\cdot}37$.

Two samples of *castor oil* were tried; one newly purchased gave $K = 4{\cdot}82$; the other had been in the laboratory a long time, and was dried over copper sulphate—

$K = 4{\cdot}84$.

The result of my earlier experiments for castor oil was 4·78; the result obtained subsequently by Cohn and Aron† is 4·43. Palaz gives 4·610.

Ether.—This substance as purchased, reputed chemically pure, does not insulate sufficiently well for experiment. I placed a sample purchased from Hopkin and Williams as pure, over quicklime, and then tested it. At first it insulated fairly well, and gave $K = 4{\cdot}75$, in the course of a very few minutes $K = 4{\cdot}93$, the insulation having declined so that observation was doubtful. After the lapse of a few minutes more observation became impossible. Prof. Quincke in his first paper gives 4·623 and 4·660, and 4·394 in his second paper.

Bisulphide of Carbon.—The sample was purchased from Hopkin and Williams, and tested as it was received—

$K = 2{\cdot}67$.

Prof. Quincke finds 2·669 and 2·743 in his first paper, and 2·623 in his second. Palaz gives 2·609.

Amylene.—Purchased from Burgoyne and Company—

$K = 2{\cdot}05$.

The refractive (μ) index for line D is 1·3800,

$\mu^2 = 1{\cdot}9044$.

Of the benzol series four were tested: *benzol, toluol, xylol*, obtained from Hopkin and Williams, *cymol* from Burgoyne and Company.

In the following table the first column gives my own results, the second those of Palaz, the third my own determinations of the refractive index for line D at a temperature of 17·5deg. C., and the fourth the square of the refractive index:—

			μ.	μ^2.
Benzol	2·38	2·338	1·5038	2·2614
Toluol	2·42	2·365	1·4990	2·2470
Xylol	2·39	—	1·4913	2·2238
Cymol	2·25	—	1·4918	2·2254

For benzol Silow found 2·25, and Quincke finds 2·374.

The method employed by Palaz is very similar to that employed by myself in these experiments; but, so far as I can ascertain from his paper, he fails to take account of the induction between the case of his fluid condenser and his connecting wire. He also supports the inner coating of his fluid condenser on ebonite; and, so far as I can discover, fails to take account of the fact that this also would have the effect of diminishing to a small extent the apparent specific inductive capacity of the fluid. Possibly this may explain why his results are in all cases lower than mine. Determinations have also been made by Negreano (*Comptes Rendus*, Vol. CIV., 1887, 423) by a method the same as that employed by myself.

Three substances have been tried with the guard ring condenser—double extra dense flint glass, paraffin wax, and rock salt. The first two were not determined with any very great care, as they were only intended to test the convenience of the method. For double extra dense flint glass a value 9·5 was found; the value I found by my old method was 9·896. For paraffin wax 2·31 was obtained, my previous value being 2·29. In the case of rock salt the sample was very rough, and too small; the result was a specific inductive capacity of about 18, a higher value than has yet been observed for any substance. It must, however, be received with great reserve, as the sample was very unfavourable, and I am not quite sure that conduction in the sample had not something to do with the result. In the experiments with the guard-ring condenser the disturbing effect of the connecting wire was not eliminated. My thanks are due to my pupil, Mr. Wordingham, for his valued help in carrying out the experiments.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XLVII.

BY OLIVER HEAVISIDE.

(Concluded.)

Two non-distortional circuits of different types in sequence. Persistence of electrification, momentum, and energy. Abolition of reflection by equality of impedances. Division of a disturbance between several circuits. Circuit in which the speed of the current and the rate of attenuation are variable, without any tailing or distortion in reception.

If two non-distortional circuits of different types be joined in sequence, a wave passing along one of them will, on arrival at the junction, be usually split into two, a transmitted and a reflected wave. Let, in the former notation, V_1, V_2, V_3 denote the potential-differences in corresponding elements of the incident wave in the first circuit, the reflected wave in the same, and the transmitted wave in the second circuit. The sole conditions at the junction are that V and C shall not change in passing through it. Thus,

$$V_1 + V_2 = V_3, \qquad C_1 + C_2 = C_3 \quad . \quad . \quad (73d).$$

Now let L_1v_1 and L_2v_2 be the impedances of the two circuits, L_1 and L_2 being the inductances per unit length, and v_1, v_2 the speeds of the current. Put the first of (73*d*) in terms of the currents. Thus,

$$L_1v_1 (C_1 - C_2) = L_2v_2C_3 \; ; \quad . \quad . \quad . \quad . \quad (74d)$$

showing that the momentum of the incident disturbance equals the sum of the momenta of the reflected and transmitted disturbances. Corresponding lengths are compared, of course, proportional to the speed of the current. The condition of continuity of V is therefore identical with that of persistence of momentum.

Next, put the second of (73*d*) in terms of potential-differences. Thus,

$$S_1v_1(V_1 - V_2) = S_2v_2V_3 \; ; \quad . \quad . \quad . \quad . \quad (75d)$$

which expresses that the electrification suffers no loss by the splitting. The condition of continuity of C is therefore equivalent to that of the persistence of electrification.

Multiply the first of (73*d*) into (75*d*); the second of (73*d*) into (74*d*); the two members of (73*d*) together; and (74*d*) into (75*d*). The results are

$$\left. \begin{array}{c} S_1v_1(V_1^2 - V_2^2) = S_2v_2V_3^2 \; ; \quad L_1v_1(C_1^2 - C_2^2) = L_2v_2C_3^2 \; ; \\ V_1C_1 + V_2C_2 = V_3C_3 \; ; \end{array} \right\} \quad (76d)$$

which are equivalent expressions of the fact of persistence of energy, while the last of (76*d*) is the equation of transfer of energy. That it should be equivalent to the others will be understood on remembering that the energy is transferred at speed v_1 or v_2, according to position.

We have, therefore, three things that persist, electrification, momentum, and energy, and these are expressed most simply by the two equations (73*d*) and by their product. If the continuity of V could be violated at the surface across the

Digitized by Google

dielectric common to the two circuits at their junction, there would be a surface magnetic current; and if the continuity of C could be violated, there would be a surface electric current. These statements are implied in the general equations

$$-\text{curl}\,E = 4\pi G, \qquad \text{curl}\,H = 4\pi\Gamma, \quad . \quad . \quad (77d)$$

where E and H are the electric and magnetic forces, Γ and G the electric and magnetic currents. That is, tangential continuity of E implies normal continuity of G (or of the induction, since it, like G, can have no divergence); and tangential continuity of H implies normal continuity of Γ, and therefore, in our special case, of electrification. In fact (73*d*) express the same facts as (77*d*) do generally.

Now the continuity of V and C is violated at the boundaries of an isolated disturbance (*e.g.* V = constant in a certain part of the circuit, and zero before and behind). Then we do have the surface electric and magnetic currents on the front and back of the disturbance. It should, however, be stated that the conception of an isolated disturbance is merely employed for convenience of description and argument. Practically, there cannot be abrupt discontinuities; we must make them gradual. Then the surface currents become real, with finite volume-densities.

The ratio of the reflected to the incident wave is given by

$$V_2/V_1 = (L_2v_2 - L_1v_1)/(L_2v_2 + L_1v_1), \quad . \quad . \quad (78d)$$

and is positive or negative according as the impedance of the second circuit is greater or less than that of the first. The abolition of reflection is therefore secured by equality of impedances, irrespective of any change of type that does not conflict with this equality. Every element of the transmitted wave therefore carries forward, in passing the junction, its potential-difference, current, electrification, momentum and energy unchanged, but is changed in length in the same ratio as the speed of the current is changed.

In a similar manner we can determine fully what happens when a disturbance travelling along one non-distortional circuit is caused to divide between any number of others of any types. We have merely to ascertain the magnitude of the reflected wave in the first circuit. Let V_1 and U_1 be the incident and reflected waves. Then, corresponding to (78*d*) we shall have

$$U_1/V_1 = (I - L_1v_1)/(I + L_1v_1), \quad . \quad . \quad . \quad (79d)$$

where I is the resultant impedance of all the other circuits (instead of L_2v_2, that of one only), viz. the reciprocal of the sum of the reciprocals of their separate impedances. Knowing thus U_1 in terms of V_1, we know their sum. But this is the common potential-difference in all the transmitted waves, which are therefore known, since by dividing by the impedance of any circuit we find the current. As regards the attenuation as the disturbances travel away from the junction, that must be separately reckoned for each circuit, according to the value of R/L, in the way before described. There will be found to be the previously mentioned persistences, provided all the waves are counted, including the reflected in the first circuit.

Now put any number of non-distortional circuits in sequence. If their impedances be equal, we know, by the above, that a disturbance will travel from end to end without any reflection at the junctions. It will vary in its length and in its speed, and also in the rate at which it attenuates, but there will be no tailing, however many changes there may be in the values of R and L. By pushing this to the limit, we arrive at a circuit in which R and L vary in an arbitrary manner, (functions of *x*), whilst K varies in the same way as R, and S in the same way as L. The impedance is a constant, but the rate of attenuation and the speed vary in different parts of the circuit.

If we start an isolated disturbance at one end, it will travel to the other without tailing. But it will be distorted on the journey, owing to the variable speed of its different parts and the variable attenuation. But as regards the reception of the wave, there is no distortion whatever. For, on arrival at the distant end, where we may place the absorbing resistance, every element of the wave has gone through the same ordeal precisely, passing over the same resistances in the same sequence and at the same speed at corresponding places, so as to arrive at the distant end in the same time, attenuated to the same extent. Similarly there is no intermediate distortion as regards the succession of values of V and C at any one spot. There is only distortion when it is the wave as a whole that is looked at, comparing its state at one instant with that at another. And if we should cause this wave to start in a uniform circuit, then pass into an irregular one as just described, and finally emerge in a uniform circuit again, it will have then recovered its original shape, every part being attenuated to the same extent.

As regards the time taken to pass over a distance *x* in the variable circuit, we have to solve the kinematical problem: given the path of a particle, and its speed at every point, find the time *t* taken. Thus,

$$t = \int dx/v,$$

taken between the proper limits, wherein *v* is to be a function of *x*. The attenuation suffered in this journey is more easily expressed. Go back to the former case of any number of uniform non-distortional circuits of equal impedance joined in sequence. The attenuation produced in passing through any number of them is the product of their separate attenuations, *i.e.*,

$$\epsilon^{-R_1/Lv} \times \epsilon^{-R_2/Lv} \times \ldots = \epsilon^{-\Sigma R/Lv}, \quad . \quad . \quad (80d)$$

where R_1, R_2, . . . , are the resistances of the separate sections, and *Lv* the common value of the impedance. As this is independent of the number of sections or their closeness, we see that in our variable circuit the attenuation in any distance is expressed by the right member of (80*d*), wherein ΣR represents the total resistance of the circuit in that distance, or $\int R dx$ between the proper limits, R being a function of *x*.

The above given demonstration of the properties of the variable non-distortional circuit, which is rather a curiosity, depends entirely upon our previous proof that the abolition of reflection at the junction of a pair of simple non-distortional circuits is obtained by equality of impedances irrespective of any change that may take place in the resistances. The following is also of some use. Go back to the fundamental equations

$$-\nabla V = (R + Lp)C, \qquad -\nabla C = (K + Sp)V; \quad . \ (81d).$$

wherein ∇ means *d/dx*, and *p* means *d/dt*. Now *assume* V = *Lv*C, making them become

$$\left.\begin{aligned} -\nabla(LvC) &= L\,(R/L + p)\,C, \\ -\nabla C \quad &= S\,(K/S + p)\,(LvC). \end{aligned}\right\} \quad . \quad . \quad (82d).$$

If our assumption can be justified, these equations must become identical. They do become identical if R/L = K/S, and *Lv* = constant; becoming

$$-v\nabla V = (R/L + p)V. \quad . \quad . \quad . \quad . \quad (83d)$$

This is for the positive wave. The assumption V = − *Lv*C again makes (81*d*) identical under the same conditions, the resulting equation being (83*d*) with the sign of *v* changed. The necessary conditions may be written

$$R/K = L/S = (Lv)^2 = \text{constant}; \quad . \quad . \quad (84d)$$

and since we have made no assumption as to the constancy of R, L, K, and S, we see that R and L are left arbitrary, any functions of *x*. Or, what comes to the same thing, R/L and *v* are arbitrary, making the attenuation and the speed variable, but without any tailing.

A third way is to examine what happens when we place a bridge of conductance *k* across the junction of two non-distortional circuits of different types but of the same impedance, along with a resistance *r* in the circuit at the same place. The two conditions, using the former notation, are

$$\left.\begin{aligned} V_1 + V_2 &= (1 + r/Lv)V_3, \\ V_1 - V_2 &= \{1 + (k/Sv)(1 + r/Lv)\}V_3; \end{aligned}\right\} \quad . \quad . \quad (85d)$$

from which

$$\left.\begin{aligned} V_1/V_3 &= 1 + r/2Lv + (k/2Sv)(1 + r/Lv), \\ V_2/V_3 &= r/2Lv - (k/2Sv)(1 + r/Lv), \end{aligned}\right\} \quad . \quad (86d)$$

which give the ratios of incident and reflected to transmitted wave. We destroy the reflection by

$$r/Lv = k/Sv + rk,$$

Digitized by Google

and then the attenuation is

$$V_3/V_1 = (1 + r/Lv)^{-1}$$

due to r and k. An infinite number of these r's and k's in succession, placed infinitely close together, leads to the expression (80*d*).

We can also go a little way towards finding what occurs when the only condition is Lv = constant, so that there is tailing. For we then have, at a single junction

$$V_3/V_1 = (1 + r/2Lv)^{-1}(1 + k/2Sv)^{-1} ;$$

and therefore, when the distribution of r and k is made continuous, the attenuation of the head of a disturbance in passing through any distance is

$$\epsilon^{-R_1/2Lv} \times \epsilon^{-K_1/2Sv},$$

if R_1 be the total resistance and K_1 the total conductance of the leakage in that part of the circuit. But we cannot similarly estimate to what extent the total charge and momentum have attenuated, as we could when the circuit was uniform, because the attenuation now occurs at a different rate in different parts of the tail, and we are not able to trace the paths followed by the different parts of a charge as it splits up repeatedly. The determination of the exact shape of the tail is of course an infinitely more difficult matter. But an approximation may be obtained by easy numerical calculations, if we concentrate the resistance and leakage in a succession of points.

P.S. to Section XLVI.

CORRECTIONS. By an oversight, the corrections to the proof of Section XLVI. (October 7, 1887) were not carried out. The following are necessary :—

Page 459, 2nd column. In second line after equation (60*d*), for V_2V_1 read V_2/V_1. Equation (62*d*), for V_1V_3 read V_1/V_3.

Page 460. In third line of second column, for n read x. In eighth line after equation (67*d*), for r read r. Four lines later, for t S/K read S/K. In equations (69*d*) and (70*d*), for V_α read V_0a ; also in second line before (69*d*). In (70*d*), for n read x.

NOTE (Nov. 30, 1887).—The author much regrets to be unable to continue these articles in fulfilment of Section XL., having been requested to discontinue them.

SOUTH KENSINGTON.

EXAMINATIONS OF THE SCIENCE AND ART DEPARTMENT.

(*Continued from page 17.*)

Voltaic Electricity.

30. When a coil of wire is connected in circuit with a battery and a tangent galvanometer, the galvanometer shows a deflection of 45°. If the wire is replaced by resistances of 24 and 25 ohms in turn, the deflection is 46° in the first case and 44° in the second. Find the resistance of the wire.

Tan 44° = 0·966 ; tan 45° = 1·000 ; tan 46° = 1·036.

Answer. Let r be the required resistance of the wire, and R that of the battery and connections; then, if the E.M.F. of the battery be supposed to remain constant, we have

$$\frac{E}{R+25} : \frac{E}{R+r} : \frac{E}{R+24} = \tan 44° : \tan 45° : \tan 46°$$
$$= 0·966 : 1·000 : 1·036,$$

which give

$$\frac{R+r}{R+25} = \frac{0·966}{1·000}$$
$$\frac{R+r}{R+24} = \frac{1·036}{1·000} ;$$

or,

$$0·034\,R + r = 24·150,$$
$$-0·036\,R + r = 24·864.$$

Whence by subtraction $\quad ·07\,R = -·714$;

or, $\quad R = -10·2$

The battery resistance would therefore have to be negative in order to fulfil the conditions of the problem, and this would, of course, be practically impossible. But a question of this kind forms a somewhat severe test of a candidate's confidence in his work, as if he were doubtful about the correctness of his method he would naturally conclude that such a result was due to some error on his own part.

Substituting the value obtained for R in one of the equations connecting r and R, say

$$0·034\,R + r = 24·15,$$

we obtain $\quad -0·3468 + r = 24·15,$

or $\quad r = 24·4968$ ohms.

31. A current is passed through a coil of wire and through a voltameter arranged in series with it. If the strength of the current is altered so that the heat produced per minute in the coil of wire is doubled, show what change will be produced in the rate at which chemical action takes place in the voltameter.

Answer. Let H_1 and H_2 be the quantities of heat produced in the two cases by the currents C_1 and C_2 respectively. Then since the amount of heat produced is proportional, other things being equal, to the square of the current strength, we have

$$\frac{C_1^2}{C_2^2} = \frac{H_1}{H_2} = \frac{1}{2}.$$

Therefore $\quad \frac{C_1}{C_2} = \frac{1}{\sqrt{2}}.$

And the rate at which chemical action takes place is proportional to the current strength, so that the ratio of the rate of chemical action in the second case to that in the first case will be as $\sqrt{2} : 1$.

32. If an increase of the resistance of a circuit by 10 ohms causes the strength of the current to decrease from 5 to 2, find the total resistance of the circuit after the change.

Answer. When the E.M.F. remains constant, the current strength is inversely proportional to the resistance, so that if r be the original resistance of the circuit in ohms, we have

$$\frac{r+10}{r} = \frac{5}{2},$$

which gives $\quad r = 6.\dot{6}.$

And therefore $r+10$, the total resistance after the change, is equal to 16·6.

33. Two bars of bismuth A and B are attached to the extremities of a bar of antimony, and a current is passed from A to B. Is there any difference, and, if so, what, between the effects produced at the two junctions? How does the effect in each case depend on the strength of the current?

Answer. Let the current from the battery r flow through the system of bars from A to B, as shown in Fig. 28. Then the junction C, where the current flows from bismuth to antimony, will be cooled by the passage of the current, while the junction D will be heated by the passage of the current from antimony to bismuth, this is known as the Peltier effect. The effect at C will be less than the true amount due to the Peltier effect, and that at D will be greater owing to the heat produced in the ordinary way by the resistance of the circuit. The Peltier effect at either junction is approximately proportional to the strength of the current, and the heat due to resistance will, when the current is increased, increase in the ratio of the square of the current.

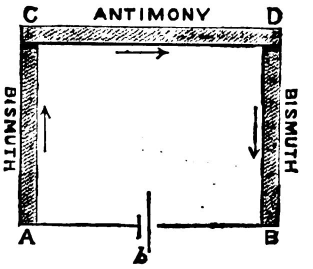

FIG. 28.

34. A piece of wire is bent into the form of a rectangle, and the ends are joined. It is laid upon a horizontal table with two sides pointing magnetic north and south. If the rectangle be turned about the east side as a hinge so as to lie on the table to the east instead of to the west of it, what will be the direction of the

Digitized by Google

current which circulates in the wire during its motion in consequence of the earth's magnetism ?

Answer. Let the rectangle A B C D (Fig. 29) be laid on a horizontal table, with its sides C A, D B, pointing magnetic north and south, as shown in the diagram. If it be turned about the east side B, D, as a hinge, a momentary induction current, due to the earth's magnetism, will flow along the hinge from north to

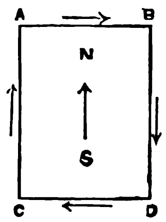

Fig. 29.

south, or the current round the rectangle will be in the direction A B D C, as shown by the arrows.

ELECTRICITY IN MEDICINE.

[A COMMUNICATION.]

Electricity as a therapeutic agent in medicine and in surgery has now gained an acknowledged place.

Electropathy, at first only timidly courted by medical men, was apt to be looked upon but a few years ago as the practice of an occult art. Little was known about electricity—spoken of indifferently as a current, a fluid, or an imponderable agent—not much of its effects or influence, nothing whatever of its mode of action as a curative agent. If even yet we may not be quite certain as to what electricity really is, or of the extent of its curative powers, or, again, of its mysterious beneficial action in health or disease, we cannot but acknowledge that electropathy has made giant strides of late. It may now, indeed, be classed as an exact science ; for, after all, what if we do not know the actual way in which the electric current works on the human system ? Are we not quite as much in the dark on this head, at least with regard to many, if not most drugs? It is only just beginning to dawn on the profession why and how alkaloids—vegetable or animal—so powerfully affect the living organism. The time, perhaps, may come when we shall know all about electricity ; but in the meantime we know that electricity does act beneficially in many cases. So far as this goes we have plenty of evidence in support, and for the moment this should suffice us—sufficient, at least, to make us adopt it as a useful servant, while we grope diligently into its history, and endeavour to grasp more accurately and definitely the mystery as yet hidden from us. There is a great secret unguessed, but we need not despair of, sooner or later, wresting it from Nature.

There was a time, and no distant one either, when the use of electricity by physician or surgeon was undoubtedly dangerous. There was a distinct difficulty in prescribing accurate doses ; the strength of each battery differed, and was by no means regular in its action, and it was, moreover, impossible to measure or regulate the force of the current. All this is changed. Batteries are more perfect in make, their action more steady and regular, and we possess the galvanometer. Hence, definite doses may be prescribed and accurately administered. An exact method of computation has been established, and now the operator, armed with one of the new instruments with all its modern improvements, may regulate at his will, graduate the flow, and operate with the utmost precision. The patient's sensations are no longer the sole or even the principal guide to the operator. They need only be taken into consideration as a useful index of the patient's susceptibility to electricity.

At first merely valued as a means of diagnosis in death or paralysis, it is now known as a remedy in many maladies. Its inestimable use in muscular and nervous derangements is now no longer questioned. It is a *stimulating* and a *sedative tonic*, for it stimulates the action of the nerves and muscles, promotes nutrition, and stills pain. Electricity will act as a stimulant where all other specialities have failed ; so, too, will it happily replace anodynes when they have been tried in vain, for in the hands of a skilful practitioner it is a powerful and speedy soother.

Adopted as a remedy in great evils and in small ones, it frequently answers all expectations. Of paralysis it has been said, "If the paralysed muscles retain their electro-contractility and sensibility, and so show that they have not passed into that state of fatty degeneration into which they always tend to pass eventually, there appears to be scarcely any limit to the time in which improvement and even complete recovery is possible." Then let us pause and consider its wonderful efficacy in neuralgic disorders as a reliever of mental and bodily depression and fatigue. But electricity is general in its action, it does not merely affect the muscular and nervous systems. Coming to smaller matters, we hear of its dissipating chilblains. The Americans have invented and widely adopted a mechanical electro-massage instrument with very marked beneficial results.

In surgery what has not been done with electricity ? We have the cautery heated only after it is properly and safely placed, and kept at a uniform heat during the whole duration of the operation. Then the knife, the *ecraseur* or loop, and the needles—all and each one of these instruments having the same great advantages attached to their use as that so noticeable in the electric cautery. In delicate operations, where hemorrhage is looked for and dreaded, electricity is invaluable, for whether the knife or the *ecraseur* be employed, the flow of blood is often entirely prevented, and always materially diminished—undisguised blessings which every surgeon will recognise.

Although many advocates of electropathy are apt to push their views too far—for we by no means recognise the use of electricity on every occasion as a sort of universal agent, either in medicine or surgery—yet we think that a great future lies before the really scientific medical electrician, who, while deeply imbued with the importance of his study, at the same time avoids its indiscriminate use. So much has already been done, and in so remarkably short a lapse of time, that careful experiments and diligent observation and study cannot fail to enhance the medical value of this mysterious but undoubtedly beneficial agent.

TESTS OF THE JULIEN ACCUMULATOR.*

BY GEORGE B. PRESCOTT, JUN

The following electrical measurements of the Julien accumulator were made in order to determine its adaptability to a certain class of work, and to that end it has been sought to ascertain with as much accuracy as possible its precise rate of doing work, the total amount which it is capable of performing, and its efficiency under various conditions as a transformer of energy. For this purpose I employed five of the standard cells of the following dimensions, as determined by my own measurements, viz.:—

Weight of cell complete	38lb.
,, grids and active material	27·5lb.
,, electrolyte	4 5lb.
,, glass containing jar	6lb.
Number of positive plates	9
Dimensions ,, ,,	$5\frac{13}{16} \times 5\frac{13}{16}$lb.
Active surface of positive plates	4·25 sq. ft.

Three of the above cells were furnished directly from the works, especially for this test, and the remaining two were received from the works at the same time by Mr. Weston. These latter were incorporated into this test, as it was deemed that greater accuracy could be attained by the use of a larger number of cells. It is assumed, of course, that all were thoroughly formed and in prime condition.

Three of the cells were filled with dilute sulphuric acid (free from nitric acid), of the density of 15deg. Baumé ; the electrolyte of the remaining two cells had a density of 23deg. Baumé. The degree of density of the electrolyte had no perceptible influence upon the E.M.F. of the accumulators, and the conditions of the test were such as to make it inconvenient to determine whether the regularity of discharge was influenced by this condition.

The cells were charged by a Weston dynamo driven at a uniform speed, and were discharged through German silver wires adjusted to suit the required conditions. E.M.F. and potential difference (P.D.) were measured by means of a white pattern Thomson quadrant electrometer, standardised by Weston-Clark standard elements. All readings are given in legal units, and time was accurately noted. Current was measured by a magnet ammeter, reading to within two-tenths ampere, which was carefully calibrated at the beginning of the test.

The cells were never discharged at a rate exceeding 30 amperes, as that was the limit of reliable reading on the ammeter ; but the general results are such as to indicate that the normal output of these cells should not be allowed to exceed that rate if anything like a reasonable efficiency is desired. No doubt this output may be momentarily increased up to 40 or 50 amperes without immediately endangering the stability of the cell, but such increase will always be obtained at a large sacrifice of its efficiency.

Five complete tests—charge and discharge—were made, the

results of which are given in the accompanying table. The significance of these figures is so obvious that I hardly need to point out to you the general conclusions to be drawn therefrom.

The first charge was discontinued about one half-hour after gas began to be freely evolved from the cells, and the rate of charging was approximately that given by the makers, viz., 18 amperes. The discharge was maintained at about 20 amperes, and the test showed a return of nearly 70 per cent. of the total energy absorbed. The second and third tests were also made at the normal rate of charging, which was, however, carried to a higher point than in the first test, and continued for a longer period after gas began to be evolved. They were discharged at the rate of about 30 amperes, and while a somewhat greater output was shown over the preceding tests, the energy returned fell off to 61 per cent. In the fourth test the charging was accomplished at the normal rate, but was continued for several hours after the evolution of gas, and until nearly 400 watt-hours of energy had been expended in each cell. The total output thereby obtained did not, however, exceed that of the preceding tests in which much less work had been done in charging—the efficiency falling to 54 per cent.—thereby clearly indicating that the limit of charge is not much over 300 watt-hours per cell. The output might be slightly increased by increasing this charge at a low rate, but under the necessary practical conditions of quick charging, any increase would be obtained at such an enormous loss that it would be, commercially, out of the question.

The fifth and last test was carried out without special regard to makers' instructions, although, with the exception that the density of the current was greater, the general effects were about the same as if the cells had been charged at constant potential. The charging current was kept at 26 amperes until there was a mild evolution of hydrogen, and then gradually decreased so as to maintain the evolution of gas about constant. When the current had thus been reduced to 10 amperes it was allowed to stand at that strength until the gas began to be freely evolved, when the charge, according to my belief—having reached its economical limit, was discontinued. The evolution of gas represents the expenditure of energy, and as it is dissipated beyond the reach of recovery such evolution means direct loss, and the charge cannot be carried beyond that point without a corresponding loss in the efficiency of conversion. I have not seen this point noted in any of the numerous papers on accumulators which I have read, but I assume that it must be obvious to every one. The high efficiency of 95 per cent. shown by this last test is chiefly due to the low rate of discharge, which never exceeded 10 amperes, but was largely increased by the discontinuance of the charge at 260 watt-hours before the loss of much gas. It was, no doubt, still further raised by the cells having recovered somewhat from the previous discharge, which had been effected at a high rate, and thus an abnormally large output was obtained, although discharged to the same potential in both cases. That is to say, when the cells are discharged at a high rate their potential falls suddenly to the normal limit. When discharged slowly the potential falls gradually to the limit. In the former case, after remaining open for a while, there was considerable recovery, as illustrated by redischarge, whilst in the latter case there is hardly any. Therefore, it would appear that the efficiency given for test No. 5 is higher than its true efficiency, owing to an excess of residual charge that could not be easily allowed for.

The effect of lapse of time between the charging and discharging of the accumulators could not be accurately determined without extending the tests for a considerably longer period of time. The difference in loss of efficiency between an immediate discharge and one after the lapse of fifteen or twenty hours (see tests 2 and 3) is, however, very small, although if the cells are not thoroughly insulated it might amount to considerable.

From the figures of the tests and the preceding considerations it is obvious that almost any degree of efficiency may be obtained from these accumulators. In fact, it is well known that the maximum efficiency of any accumulator is attained when the rate of charging and discharging is a minimum ; in other words, when the power expended or rate of doing work is a minimum. It is therefore necessary to adopt some standard working rate for these cells, and then determine their capacity and efficiency on the basis of this rate of working. The normal output of the cells should not—as already determined—exceed 30 amperes, and as the average E.M.F. of the cells is about two volts, it is obvious that the average rate of working must not exceed 60 watts per cell. At this rate the capacity of the cells will not exceed 110 ampere-hours (see tests), and as the average P. D. during discharge is 2·03 volts, the total work done by each cell will not exceed 225 watt-hours.

Again, considering the figures of the tests, and taking into account the system of working the accumulators which you have in view, their efficiency at the above rate of working will be somewhat between 60 and 70 per cent. For ordinary working on the assumption that abnormally large discharges will be balanced in effect by abnormally small ones, the efficiency of the accumulators will probably closely average 65 per cent., and I think this figure a safe one to estimate upon.

On the above basis the following figures are self-explanatory : —

For a Single Cell.

Rate of working	0·0804 h.-p.
Time of working at this rate	3·75 hours.
Total work..	0·3016 h.-p.
Battery per horse-power hour	126lbs.

Thus 38 cells will weigh 1,444 pounds, and will develop 11·46 horse-power hour, which, expended at the rate of 60 watts per cell, is equal to three horse-power for 3·82 hours. Any loss in secondary conversion must, of course, be deducted from these values.

As to the permanency of the cells, both as regards mechanical durability and electrical efficiency, time alone can report.

"A TALK ON TRAMWAYS."

At the meeting of the New York Electrical Society, held on November 30, Mr. Holroyd Smith gave a "Talk on Tramways," in which he treated the subject of street railroads first in a general way, and then with special reference to the electrical method. In beginning his address, Mr. Smith said that too much attention cannot be given to the fact that in electrical railroading the electrician occupies the second place to the engineer, and that the past failures in electrical railroading have been due to the fact that electricians, pure and simple, have gone into the domain of engineering without sufficient knowledge to guide them. In other words, the electrician must not expect to succeed in working tramways unless he studies the engineering problems as well. Mr. Smith, in taking up the subject generally, drew attention to the fact that American railroads, or tramroads, were the necessary outcome of the generally bad ordinary roads, whereas in England the roads are uniformly good. While in America the centre bearing rail is employed almost universally, in England and abroad generally such a rail would not be permitted, and recourse must be had to the grooved rail. Hence, while with American cars and rails the coefficient of traction amounts to about only 8lb. to the ton, the English rail requires 23lb. to the ton, so that these things must not be lost sight of in designing cars. It will thus be seen that conditions vary considerably in different countries, even when seemingly they are quite alike. Mr. Smith asserts that the increased power claimed for the driving motors is due to the over-estimation of the power required to move the car.

Digitized by Google

Mr. Smith then entered into the consideration of traction by horses, compressed air, steam and cable, and deplored the fact that while in England the statistics of running expenses of horse-car lines were well-known and published in Duncan's *Tramway Manual*, we had no such source of information, and it was with the greatest difficulty that any reliable figures could be obtained with regard to the subject on American lines. Mr. Smith stated that as a rule in England a 2-horse car running for 14 hours a day required 10 horses. These horses cost £30, and had an average life of three years. In discussing the question from the electrical standpoint, Mr. Smith drew attention to three essential points that have to be considered :—1. Safety to the public. 2. Efficiency. 3. Economy.

Taking up the storage battery first, Mr. Smith held the position that even if the battery could be successfully worked, it would cost one-third more to equip and run a line on this system than to put down a conduit, and especially would this be the case where traffic is very heavy. Mr. Smith was of the opinion that of the various systems the overhead system was the best, taking all into consideration ; but the great danger in its use lay in the tendency to do slipshod work. The difficulties met with at crossings and switches in railway work where conductors of opposite polarity met in a horizontal plane are overcome by placing the conductors in a vertical plane, so that even if contact does occur it can only happen between two positive or two negative conductors. Mr. Smith finally described a new method of his own which was designed to overcome all the objections to both the overhead and underground circuits, and which, without the use of the storage battery, is arranged to supply the motor on the car with electricity. This system, which was only hinted at by the speaker, will no doubt attract some attention in the future.

In the discussion which followed, Mr. T. W. Rae spoke of the experiments made on cars in this city by Mr. C. E. Emery, the well known engineer, who found that the coefficient of traction was 12½lb. per ton ; and General Q. A. Gilmore states that the general average for the whole country is 16⅔lb. per ton.

Mr. R. G. Blackwell, whose opinions on this subject are well known, deprecated the use of the storage battery entirely, and, in replying to a question, remarked that the delay in the construction of the Fulton-street road in this city, undertaken by the Bentley-Knight Company, was due to legal complications ; and that all the material required for the road was in store in this vicinity, ready to be applied at the earliest notice.

Mr. C. O. Mailloux, in replying to Mr. Blackwell, detailed the experiments which are now going on upon the Madison Avenue line in this city on a car equipped with 120 cells of Julien storage battery, and which ran from 85th-street to Harlem Bridge and back, on a run of 40 miles, with a drop of but two volts. Mr. Mailloux stated that the Brussels Tramway Company are now operating 10 cars of this system, and that before many months have elapsed New York will see as many storage cars in operation. Mr. Mailloux drew special attention to the fact that storage batteries were well adapted to long lines on account of the large conductors required with the overhead and underground systems, where the drop of potential has to be made as small as possible.

Mr. Holroyd Smith confirmed this statement of Mr. Mailloux, but he still claimed that the use of the storage battery was only a transient one. In reply to a question by Mr. Davidson as to whether a conduit had ever been operated in this country, Mr. R. G. Blackwell referred to the experimental line operated in Cleveland on the Bentley-Knight system, and carried on through snow, ice, and water without trouble. Mr. Smith also confirmed this fact, and stated that the last winter had been most severe in Blackpool, England, where his road was in operation ; but notwithstanding this, the current had practically not stopped in three years since the road went into operation.

THE LIGHTING OF THE GRAND CENTRAL RAILWAY STATION IN CINCINNATI.

A COMPARISON OF GAS AND ELECTRICITY.

The following report has been furnished by Mr. J. W. Hill to the President of the Cincinnati Gaslight and Coke Company :—

I have the honour to submit herewith a complete detailed report of the results obtained from the recent test of the Edison electric light plant at the Grand Central Station in this city. As the compilation of the results appears quite voluminous, and may prove a little tiresome to follow out in all its details, I thought it best to submit with it this summary.

The test covered an interval of sixteen days ; the first eight being assigned to the Gas Company, and the second eight (of which I had special charge) from 6 a.m. October 11 to 6 a.m. on October 19, or 192 consecutive hours. During the whole of this time careful observations were made of the lights in service, the average illumination power of the lights, the power required to produce the light, and the cost of its production.

During this test the steam used for operating the elevator pumps, and that for heating the buildings was taken from a separate set of boilers, leaving one battery to be used exclusively in furnishing steam to the engines used in driving the dynamos, and the cost of which was found to be as follows :—

Coke used (including fuel to start fires every two weeks) 929 bushels, at 7c.	$65	03
Water to boilers, including waste to sprinkle ashes and clean boilers, 38,408·16 galls., at 9c. per 1,000 galls.	3	46
Wages, two firemen, one day and one night, at $45 per month	23	68
Interest on investment and depreciation of boilers and fixtures	9	86
Total cost of steam supplied for eight days...	$102	03

In order to ascertain the cost per annum, it is necessary to determine the ratio of lighting hours which these eight days bear to the entire year. Both the bills rendered for electric lighting and the lighting time table of the gas company show the dark hours of October to be one-tenth of the entire year, which, taken as the basis of calculation, make the actual cost of steam for one year supplied by the Depot Company $3,879.30.

The charge for electric light, exclusive of steam supply, is based upon the weight of zinc, in grammes, deposited during any interval of time, multiplied by the constant 17, which gives the number of so-called "thousand candle-power" of light furnished for the interval, and for which they are, according to their contract, authorised to charge 45c. per so-called "thousand candle-power," which charge is equivalent to $7.65 per gramme of zinc transferred during eight days. The weight of zinc thus deposited—as weighed and reported by the Electric Light Company—was 21.829 grammes, which at $7.65 per gramme equals $167 for eight days, or $647.12 for the month of October, or a total cost per annum (exclusive of steam) of $6,471.25. This discrepancy between the cost, as shown by the test, and the previous actual charge made to the Depôt Company cannot be reconciled by any possible change of conditions, or any known method of computation, and certainly shows that either during this test some method was successfully adopted with a view of materially reducing the apparent cost of electricity, or that the charge heretofore made for an equal degree of illumination has been disproportionate to the service rendered ; for I am informed that for the month of October, 1886, the charge made was $926.06, and for the year $10,784.82—making the total expense of one year's electrical illumination of the depot, according to this test, $10,350.55; and according to the actual amount charged for 1886 by the Electric Light Company, $14,664.12. The average illumination of all the lights in service at the depot buildings, train shed, omnibus court, along the tracks west of the depot, and in the office and stables of the American Express Company, was equivalent to 185 15 light of 16 actual candle-power each, or 2962·4 candles. Prof. French's test of the Cincinnati gas shows it to be of 16·94 candle-power. An equal degree of illumination of gas—2962·4 candles—would require the use of 167880·86 cubic feet, which at $1.15 per 1,000 feet equals $193.06 ; or for October, $748.11 ; or for one year the total expenses would be $7,481.10.

The total registered quantity of gas actually passing the meters during the eight days' test was 214,700 cubic feet, of which 16,000 cubic feet (it is stated) was used by "thief lights" of old style lamps ; leaving the amount actually used for illuminating purposes 196,700 cubic feet, which at $1 15 equals $228.50 ; for October, $885.44 ; or for one year, $8,854.40. This shows, first, that the same degree of illumination can be obtained with gas that was given by electricity, during the recent test, with a saving of $2,869.45, or 27·72 per cent. per annum ; secondly, that using gas without limitation, affording a higher degree of illumination, the expense would be $5,809 72, or nearly 40 per cent. less than the actual cost of electrical illumination last year.

In the above estimate of cost of electricity—based on the transfer of zinc in the voltameters—it is assumed that the charge of the owners of the electric plant covers all the items of electricians' wages, interest, depreciation and profit on operation of plant, renewal of lamps, oil and waste for engines, and all other items of expense not otherwise specifically mentioned above. Should this not be the case, and other items of expense, of which I am unaware, are borne by the Depot Company, then the cost and disparagement of the electric light becomes greater than I have shown it to be.

Apart from the cost of the light produced by the electric plant, there are other points which have been pointed out in my general report, and to which I take the liberty of referring in this summary.

During the weighing of the zinc plates of the voltameters used by the Electric Light Company to measure the amount of light furnished to the Depot Company, the phenomenon, which I am informed is not unfrequent, was developed of the diminishing plate gaining instead of losing (as it should if the meter is working properly) in weight ; showing an apparent reversal of current for certain meters, the custom in cases of this kind being (as I am informed) to take the gain in weight of the plates—which should have lost in weight—as the measure of zinc transferred. Although authorities on electrical science assert that, with a given strength of current, the rate of transfer of zinc from one plate to another in a voltameter is constant for any given time, and knowing the time and current the loss of zinc by the positive plate may be calculated from constants determined by experiment, it seems strange that the current should be reversed, as it was in the meters noted above. And this fact, of which we have ocular evidence, would indicate a state of affairs very dangerous to the pocket of the consumer of light ; for if these meters will work backwards (as it were), why should they not work forwards at a rate greater than that assigned by theory, and cause a registration of more light than is actually furnished ? If I were a consumer of electric light, I should require better

Digitized by Google

evidence than that before me now to induce me to accept the records of these meters as a reliable statement of the light furnished.

Another fact to which I will again refer is the great range in candle-power of the lights, with a slight change in the intensity or pressure of the electric current. Thus the (D) 32 nominal candle-power lamp with the filament placed at an angle of 45deg. to the plane of the photometer bar, with a resistance producing 99 volts, the current was 1·05 ampere, and the candle-power 23·94; while with a resistance producing 99 volts, the current was 1 268 ampere, and the candle-power 42·89, or nearly twice as great as in the previous test. The reduction of the resistance and current diminishes the load on the dynamos and engines, prolongs the life of the lamp, and materially diminishes the illuminating effect. Should it appear that at any time during the day or night the voltage (pressure) of the electric current is reduced below 99 volts—which I have reason, from our running record, to believe is the case—then the illumination produced will be greatly diminished from the standard, while the cost of the light to the consumer may be practically unchanged.

From a comparison of currents required to maintain the test lamps, it appears that the cost is about the same for a weak as for a strong light, or while the illuminating effect or candle-power of the light steadily diminishes with age (use), the current to maintain its incandescency remains substantially constant.

As a matter of fact, it may be shown that the current, and consequently the cost to the consumer, becomes greater with a lower candle-power. Thus:—

32 Candle-Power Lamps.

Actual candle-power.	Ampere.
62·44	1·29
30·16	1·31

Or, with a loss of illuminating effect of 52 per cent., the cost of the light is increased nearly 5 per cent.; whence the relative cost of the weaker light is 217 per cent. of the stronger light.

16 Candle-Power Lamps.

Actual candle-power.	Ampere.
36·33	0 773
21·10	0 816

Or, with a loss in illuminating effect of 42 per cent., the cost of the light is increased upwards of 5½ per cent.; whence the relative cost of the weaker light is 182 per cent. of the stronger light. Or, while the electrical energy was 1·25 × 99 = 123·75 watts for the 62·44 candle-power light, it was 1·31 × 99 = 129·69 watts for the 30·10 candle-power light; and while the electrical energy was 0·773 × 99 = 76·527 watts for the 36·33 candle-power light, it was 0·816 × 99 = 80·784 watts for the 21·10 candle-power light. The power of the driving engines and the dynamos is usually stated in watts, being the product of the horse power of the engines into the constant 746, or the product of the electric current (ampere) into its pressure or intensity (volts). Hence the more watts required to maintain a lamp, the greater the cost of the light.

With gas or kerosene a given consumption of illuminating substance furnishes a constant power of light; while a diminished brilliancy of light is always accompanied by a reduction in the consumption of illuminating material and a corresponding reduction of cost. With the Edison light, however, it seems that a reduced brilliancy of lamp is not accompanied by a reduction of expense; but under certain conditions of lamps and service the cost may be actually greater for a light of 16-candle power than for one of twice this brilliancy. Changing the position of the filament (or loop) of the lamp, under the same conditions of current and pressure, produces a reduction of 50 per cent. in the illuminating power.

The most startling result of this test to me is the loss of over 60 per cent. in effect between the driving engines and the lamps; or of every foot-pound of work or watt developed by the engines, less than 40 per cent. is actually realised in the illuminating power of the lamps. In any other application of steam power to useful work, the relation of the work done to the power expended in doing it must come within 80 or 90 per cent. of the latter to satisfy demands for economy.

The tests of the lamps for brilliancy were made by Prof. French, of the Cincinnati University; and the tests for the current required to maintain the lamps were made by Mr. C. E. Jones, electrician, of this city, whose reports were submitted with my general report.

REGULATIONS OF THE BOSTON FIRE UNDERWRITERS' UNION.

The following regulations for the wiring of buildings have recently been drawn up by the Boston fire offices:—

Arc Light Wires.

Conducting wires must be seven feet above roofs, and placed so as to avoid ladders of the fire department and fire shutters. Whenever electric light wires are in proximity to other wires, dead guard wires must be placed so as to prevent any possibility of contact with foreign wires, in case of accident to the wires or their supports. Conducting wires must be secured to insulating fastenings, and covered with an insulation which is waterproof on the outside and not easily worn by abrasion. Whenever wires pass through walls, roofs, floors or partitions, or there is liability to moisture, abrasion, or exposure to rats and mice, the insulation must be protected with rubber, stoneware or some other satisfactory material. Wires entering buildings must be wrapped with tape, and bent in such a manner that it will prevent the water entering the building. All wires passing over or under steam, gas, or water pipes, must have a good insulation between them and the pipes. Blocks of wood are the most desirable. This rule also applies to foreign wires—they should be treated the same as pipes. Wires should go over water pipes where it is possible, so that the moisture will not settle on the wires. Hard rubber hooks are not desirable as fastenings, and tacks or staples must in no case be used for fastenings, or brought in contact with the wire. In damp places, wires must be run on glass insulators, and kept entirely clear from contact with inflammable material, and any substance likely to make a ground connection.

The use of lead-covered wires, or wires whose covering contains paraffin, is prohibited. The use of underwriters' wire will not be passed where it is concealed in any manner. It must be in plain sight—on the walls or ceilings. Wire that is covered with moulding must have a water-proof insulation that is approved by this union. Joints in wires to be securely made and wrapped with tape; soldered joints are desirable, but not essential. Wires conducting electricity for arc lights must not approach each other nearer than one foot. Care must be taken that the wires are not placed above each other in such a manner that water could make a cross connection. Cut-off boxes for arc lights must have the words *On* and *Off* marked on them. They must be placed in a well-protected and accessible place, so that they can be operated by the firemen or police.

Arc Lamps.

For arc lamps, the frames and other exposed parts of the lamps must be insulated from the circuit. Each lamp must be provided with a separate hand-switch, and also with an automatic switch, which will close the circuit and put the lamp out whenever the carbons do not approach each other, or the resistance of the lamp becomes excessive from any cause. The lamps must be provided with some arrangement or device to prevent the lower carbons from falling out, in case the clamp should not hold them securely.

For inside use, the light must be surrounded by a globe, which must rest in a tight stand, so that no particles of melted copper or heated carbon can escape, and when near combustible material, this globe must be protected by a wire netting. Broken or cracked globes must be replaced immediately. Unless a very high globe is used, which closes in as far as possible at the top, it must be covered by some protector, reaching to a safe distance above the light.

Incandescent Wires.

Conducting wires must be seven feet above roofs, and placed so as to avoid ladders of the fire department and fire shutters. All connections must be soldered and wrapped with tape. Whenever the electric light wires are in proximity to other wires, dead guard wires must be placed so as to prevent any possibility of contact with foreign wires, in case of accident to the wires or their supports. Conducting wires must be secured to insulating fastenings, and covered with an insulation which is waterproof on the outside and not easily worn by abrasion. Whenever wires pass through walls, roofs, floors or partitions, or there is liability to moisture, abrasion, or exposure to rats and mice, the insulation must be protected with rubber, stoneware or some other satisfactory material. Wires entering buildings must be wrapped with tape, and bent in such a manner that it will prevent the water entering the building. All wires passing over or under steam, gas or water pipes, must have a good insulation between them. Blocks of wood are the most desirable. This rule also applies to foreign wires—they should be treated the same as pipes. Soft rubber tube is not desirable as an insulator. Wires should go over water pipes where it is possible, so that the moisture will not settle on the wires. Where incandescent wires enter buildings, they must have double-poled safety catches as near the entrance as possible. The main wires must not be less than two and a-half inches apart, except where they are in grooves. The use of lead-covered, or wires whose covering contains paraffin, is prohibited. All wires that are fished over the ceiling, or in the walls, must have a waterproof insulation satisfactory to this union. This rule also applies to wires covered with moulding, or concealed in any manner. Where underwriters' wire is used, it must be in plain sight on the walls or ceilings. Care must be taken that the wires are not placed above each other in such a manner that water could make a cross connection. Wires that are run in damp places must be run on glass or porcelain insulators of suitable form.

For incandescent lamps the conducting wires leading to each building and to each important branch circuit must be provided with an automatic switch or cut-off, or its equivalent, capable of protecting the system from any injury due to an excessive current of electricity. These devices must be proportioned to protect the smallest wire in the loop to which they are attached. On all loops of incandescent circuits safety catches must be used on both sides of the loop, and switches on such loops should be double poled. Ceiling blocks that are used on pendant drops must have safety metals in them where flexible cord is used. Cord should have a knot tied in it with the knot on the top side of the block, so that the strain will come on the knot instead of on the connection; and where it is possible a knot should be inside of the socket, the same as the block. The small wires leading to each lamp from the main wires must be very thoroughly insulated, and if separated or broken, no attempt made to join them while the current is in the main wires. When wires are put on gas fixtures, the fixture must be isolated from the main pipe, and the insulator used for this purpose must be made so that the sediment in the gas will not form a connection over the insulating material. Chandeliers or brackets attached to any ground connection must have insulating yokes or couplings on them. Individual insulating

Digitized by Google

of lamps at the sockets will not be passed except on brackets in special cases that may be approved by the inspector.

DYNAMO MACHINES.

Dynamo machines must be located in dry places, not exposed to flyings or easily combustible material, and insulated upon wooden foundations. They must be provided with devices capable of controlling any changes in the quantity of the current; and if these governors are not automatic, a competent person must be in attendance near the machine whenever it is in operation. Each machine must be used with complete wire circuit; and connections of wires with pipes, or the use of ground circuits in any other method, are absolutely prohibited. The whole system must be kept insulated, and tested *every day* with a magnet for ground connections in ample time, before lighting, to remedy faults of insulation, if they are discovered; and proper testing apparatus must in each case be provided. This applies to both central station and isolated plants. Testing circuits for ground with a battery and bell is not considered a reliable test. Preference is given for switches constructed with a lapping connection, so that no electric arc can be formed at the switch when it is changed; otherwise the stands of switches, where powerful currents are used, must be made of some incombustible substance which will withstand the heat of the arc when the switch is changed.

MOTORS.

Wires for motors should be run exactly as for lamps on similar circuits. On low-tension circuits where motors are run in multiple safety catches must be used on each side of the circuit. On high tension circuits the same restrictions apply as for arc lamps, and suitable cut-outs must be provided. Motors must be treated as dynamos as regards insulation, flyings, dampness, &c. While these rules are intended to be complete, some cases may arise where, in the judgment of the inspector, some deviation from them may be necessary in order to secure safety.

RULES FOR RUNNING INCANDESCENT CIRCUITS FROM ALTERNATING MACHINES.

Outside wires should be treated as arc light wires, inside wires the same as incandescent circuits. Converters on alternating circuits must be outside of buildings, and must be placed high enough from the roof to prevent possible injury to firemen.

RULES TO APPLY TO THE RUNNING OF INCANDESCENT CIRCUITS WORKED FROM ARC CIRCUITS.

The running of incandescent lights or systems on arc circuits should be avoided; but wherever this is unavoidable a proper device or "distributor," such as may be approved by this union, must be provided to prevent the possibility of an excessive arc current being thrown on to any one portion of the incandescent system; such device or "distributor" *must* have the approval of this union before it is put into operation. It must remain open to inspection at all times, and no change made in any part of the installation after it has been approved without consent of this union. Only such wire as has been approved by this union shall be used in constructing lines and circuits.

Wires must be run in plain sight. In damp places they must have a waterproof covering. The positive wire or wires must be kept at least two and a-half inches from the negative wire or wires in running from the distributor or regulator to the fixtures and lamps and return; except that "twin wire" may be used for a single lamp. No wires should be run through partitions, floors or walls, without being encased in a tube of hard rubber, porcelain, or covered with tape. Soft rubber tube is not desirable as an insulator. The "safety fuses" must be so proportioned that they will melt long before the wire is heated to an unsafe degree. Dust must not allowed in the distributor-box or any of the electrical connections. The contact points should be kept clean, and care should be taken to insure solid electrical connections at all the points of contact, and all parts must be kept free to move easily. In case any defect should arise in the distributor or regulator, or the wiring thereto, it must be arranged so as to automatically and absolutely shunt off from the arc circuit at once. In working distributors, the line or circuit current must be kept at its standard amount by tests made by ampere-meter from time to time. In no case must the amount exceed the standard. Every company shall have a competent and reliable person to examine, daily, every distributor and regulator, or similar device which may in the future be applied to arc circuits.

Where incandescent lights are run on arc circuits, the following-named practices are *strictly prohibited:* Fastening or attaching electroliers or lamps to any gas fixture which may be in electrical connection with the earth. The running of *concealed* wires to the electroliers or lamps *under any circumstances*. They must be entirely open to view. The placing of any distributor box or regulator, electrolier, bracket, or lamp in such position that it may be connected in any way with any other wires, steam fittings, gas pipes, gas fixtures, &c., which may be electrically connected with the earth. The placing of the distributor, electrolier, &c., in any damp location, or in close proximity to any metal or other conductor of electricity. The building or placing of anything around the distributor or regulator so as to cut off easy access to it, or obstruct the access of air to it.

All joints after leaving the distributor or regulator must be soldered, using acid as flux. Resin will not be approved under any circumstances. All new devices should be submitted to the inspector of the union, and must be approved by him before permission can be given for their use.

While these rules are intended to be complete, some cases may arise where, in the judgment of the inspector, some deviation from them may be necessary in order to secure safety.

CORRESPONDENCE.

THE LIGHTING OF THE AMERICAN EXHIBITION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We observe that Messrs. Hornsby wrote you last week in respect to a paragraph which appeared several weeks ago in your valued paper.

Your editorial footnote clears us of having in any way inspired the paragraph objected to, and we will at once proceed to criticise the technical points raised.

In the first place we cordially endorse the remarks of Messrs. Hornsby as to the very unfavourable conditions generally. We certainly had, both of us, great difficulties to contend with, and these were entirely beyond either their control or ours; but they need not seek to excuse themselves by disparaging us. In defending ourselves, it is only necessary to state that in our contract with the exhibition authorities we had to pay a fine of 1d. per lamp per minute for any lamp out through our fault; and not a single penny has been claimed.

One more point we would like to mention. Messrs. Hornsby's indicator tests show that the I.H.P. was 348, but the number of lamps is not correctly given by them.

The total number of 2,000 candle-power lamps was 287 and not 242, and this is evidently a very fair result considering that two 50-light dynamos were running empty the whole time, and that the shafting absorbed considerable power, owing to the unstable foundations referred to by Messrs. Hornsby.

This appears to us a good record.—Yours, &c.,

LAING, WHARTON AND DOWN.

82, New Bond-street, W., December 29th, 1887.

PRIMARY BATTERIES FOR HOUSE LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Thompson is not quite convinced that the statement in Mr. Nursey's paper that "sixteen cells will maintain ten 10 candle-power Swan lamps for about twenty hours" is to be taken literally, and prefers to abide by the supposition that the work thus done represents five rather than eight electrical horse-power hours; but he frankly concedes that even with his own figures "it will be evident on referring to the table" [published in your issue of December 9th] that "when using small engines and dynamos the cost of fuel only ranges from 7 to 15 per cent. of that apportioned to labour."

That, after all, was the main, if not the only, issue discussed in a correspondence which commenced by my taking exception to Mr. Desmond FitzGerald's exaggerated attack on primary batteries for illuminating purposes, founded on his theory that they must be compared with dynamos, by means of which, "at a cost considerably under one halfpenny" [½d. is the cost of 5lb. of coal at 18s. 8d. per ton], "we can by the agency of the steam engine obtain an electrical horse-power hour."

We are now both agreed that no such crude comparison between the cost of coal and zinc has any practical application to primary batteries for house-lighting purposes.—Yours, &c.,

O. C. D. ROSS.

THE EASTERN TELEGRAPH COMPANIES' ANNUAL EAST END CONCERT.

On Saturday, 17th inst., the annual concert in aid of a fund to provide Christmas dinners for the poor of the East End of London in their own homes was given in the Great Assembly Hall, Mile End-road, Sir James Anderson in the chair.

These concerts have been given for the last seven years by gentlemen in connection with the Eastern Telegraph Companies, assisted by friends in sympathy with the object, who very kindly help considerably to cheer many an East End home by their readiness to take part in the concert and to contribute to the fund.

Sir JAMES ANDERSON commenced the proceedings by saying :—Another year has come and gone since we last met in this beautiful hall, with the same object which now brings us together, which is to extend some practical sympathy at this Christmas season to our less fortunate neighbours (cheers). All through the past history of the world there has always been, there is now, and I believe always must be, in every community a vast number of poor and unsuccessful people. All of us, excepting the very young, perhaps, know many even amongst our own friends who never seem to get their heads above water, even though they appear to struggle as bravely as those who are successful. In the language of the poet Longfellow, they seem

> "Born down by their losses,
> Weary with dragging their crosses,
> Too heavy for mortals to bear."

And no nation has ever yet solved the problem of dealing successfully with poverty and distress. There have been nations which fed the poor and the idle, with the result that the idle became the masters, and the nations perished, conquered by other nations in which every man was a trader or a fighter (hear, hear). Think it out as you will, and look back through all the ages, and you will find no record of any good thing ever done without hard work (cheers). The greatest man who has ever put warning or advice on record since the first Christmas Day dawned upon earth says : "If any man will not work neither shall he eat." No one has ever yet told us how to get through life without struggling. The battle of life is an expression as common as it is true. Do what we can, but do something, is the only advice we can take to ourselves or give to others, no matter to what class we or they belong. The Chelsea sage, the late Thomas Carlyle, put upon record something like a bitter cry : "Produce, produce, be it but the infinitesimal fraction of a product, in God's name produce it!" (cheers). You will naturally say that is all very well so far, but what is to be done with those who cannot get work, the thousands who from sickness or other causes cannot work? The answer may not be satisfactory, but I do not know of any other ; all we have to expect is the help and sympathy of relatives, friends, and fellow citizens. Fortunately in this country there is a growing band of workers seeking in many ways to find out the weary and heavy laden and carry relief and sympathy amongst them I believe there is hardly a sorrow or trial so great that cannot in some degree be soothed by sympathy (applause). When I used to voyage to what we called heathen lands I used to think that had it been my lot to be a missionary I should have learned in the native dialect to have told them the parable of the Good Samaritan. I fancied I could have rung changes in many an exhortation upon all its beautiful points. I think there is no possible equal to it to illustrate the object of our Christian religion, or of anything worth calling a religion (cheers). The Good Samaritan did not use many words, but carried the wounded man to an inn, soothed his wounds, and left means to sustain him until he recovered. I should not wonder if out of this parable there has come the common English saying, "How much do you sympathise?" There are very few in any nation rich enough to give to every charitable object. With the vast majority of even what are known as successful people, few can do more outside the demands of their own families and relations than give here a little and there a little. We are not met here to-night to plead for any heroic object. We are only met to sympathise to the extent of giving some good cheer to as many families in their own homes on Christmas Day as the sum collected will pay for. To that extent our friends who have kindly volunteered to entertain us to-night, and you who have paid to be entertained, are the good Samaritans of this occasion, and all of us have the satisfaction of knowing that we are doing something in the way of practical sympathy that cannot fail to be accepted thankfully by the families who are selected to be the recipients of the good things to be provided (loud cheers).

The speech was listened to with manifest interest and was heartily applauded.

The concert was then proceeded with and proved to be the best yet given. Mr. W. J. Finnis sang in first rate style "One night came on a hurricane," and "Oh! oh! hear the wild wind blow," the latter specially receiving hearty applause. Mr. W. H. Owen (who is a great favourite at the Assembly Hall) recited in two parts, Dickens's "Cheap Jack," with remarkable elocutionary effect. Miss Maude Snell, who upon her appearance was very warmly greeted, sang "The City of Rest" and "When

Digitized by Google

the heart is young." Miss Snell is the fortunate possessor of an exceptionally good soprano voice which she uses to the best possible advantage. Mr. Sadleur Brown sang "Tell me, Mary," and "O'er the Hills of Normandie," in faultless style, his voice being a remarkably pure one. Miss Louise Courtney rendered "Jerusalem" and "The Minstrel Boy," and Miss Ida Everard "Sing, Sweet Bird," and "The Wishing Well." Both of these ladies were heartily applauded for their songs, and they richly deserved it all, for their singing was really excellent. Mr. Guildford Dudley recited "A September Gale," and "The Jackdaw of Rheims," both of which created roars of laughter and thunderous applause. A violin solo was given by Mr. Hughes Brabant, entitled "Scène de Ballet," which was very greatly appreciated. The splendid organ was perfectly manipulated by Mr. Arthur Briscoe, who deserves the very highest commendation for his organ solo "Marche Militaire," and for the first class talent displayed as accompanist. It may here be said that a song, "Bells o' Dee," composed by this very promising musician, was sung during the evening, and was well received. Mr. J. H. D. Denham brought the programme to a close with the "Bedouin Love Song," which he sang very effectively.

In proposing a vote of thanks to Sir James Anderson for presiding, Mr. E. H. Kerwin expressed the great pleasure they had in seeing Sir James again amongst them, and thanked him for his kindness in presiding and his generosity in subscribing to the dinner fund. Mr. James Haysman (who had purchased one hundred tickets for distribution among the poor of the neighbourhood) seconded the vote of thanks, remarking that it was not the first time he had heard of Sir James's philanthropy. The vote was then put to the meeting, and was carried with acclamation.

The proceeds of the concert and the donations amounted to over £75, and on Friday last 275 deserving families received goods for a very substantial Christmas dinner, consisting of beef, suet, flour, bread, plums, currants, sugar, and some tea. The total number of persons thus fed was about 1,200.

COMPANIES' MEETINGS.

The National Company for the Distribution of Electricity by Secondary Generators (Limited).

The fourth ordinary general meeting of the shareholders in this Company was held at the offices, Warwick-street, Regent-street, on Wednesday, Mr. Wm. D'Oyly in the chair, when the report of the Directors and statement of accounts were adopted. The following is the report of the Directors of the Company:—

Shortly after the report presented to the shareholders on the 18th March, 1886, the work of the Company was seriously interrupted by infringers of the Company's patents. Acting under the advice of the most eminent counsel and the highest scientific authorities, the Directors have instituted proceedings in the English and Foreign Courts to protect the interests of the shareholders. The installation at Tours, in France, which has been working satisfactorily without interruption since January, 1886, was the object of attack by infringers, whose patent was ultimately declared invalid, the Court of Tours giving damages to the Banque d'Escompte de Paris, which held an exclusive licence to employ the company's system in France. The Directors have claimed damages from the Banque d'Escompte, whose contract with the Company your Directors have cancelled. In the month of May, 1886, the Directors were compelled to bring an action against Sir Coutts Lindsay and Co. (Limited). This action was settled upon the payment by Sir Coutts Lindsay and Co. (Limited), of the royalties claimed and costs. Near the close of 1886, Mr. Ferranti, who had been engaged as engineer by Sir Coutts Lindsay and Co. (Limited), filed a petition to revoke the Gaulard-Gibbs patent of 1882 on the ground that it interfered with his patent of 1885, alleging informalities in the specification and anticipation. Subsequently it became necessary to bring another action for infringement against Sir Coutts Lindsay and Co. (Limited) and Mr. Ferranti. These two actions have yet to be tried, and will probably be merged in one. The Directors have felt it their duty to attack two infringing patents in Germany, and have done so with success. Both in regard to the protection of the Company's patent rights in Germany and the development of the business there, the Directors have secured the co-operation of Messrs. Siemens and Halske, of Berlin. The installation at Aschersleben is working satisfactorily and has been extended. Although litigation is exceedingly costly, it is inevitable where valuable patents are concerned; but the sacrifice involved both in cash outlay and interruption to profitable work is likely to be largely compensated by future advantage. Mr. George Westinghouse, jun., who acquired the exclusive right to use the Company's patents in the United States of America, has upheld them in the United States Courts. Mr. Westinghouse is actively pushing the business; his Company in a recent letter stated—"We are quite confident that by the 1st of January, 1888, we will have more than 120,000 lamps in use with secondary generators." These 120,000 lamps are divided amongst about eighty central stations, most of them capable of extension. This is the result of little more than one year's work, producing in royalties to the Company upwards of £4,000, which must be considered most satisfactory. The Directors are glad to be able to state that in this country the trade generally have shown a desire to recognise the Company's foundation patents. Messrs. Hammond and Co. are employing the Gaulard-Gibbs system at Eastbourne and Brighton under licence from this Company; other negotiations are in progress for the extensive use of the Company's system in this country. The Directors have been enabled to close the small works in Castle-street since entering into a manufacturing contract with Messrs. Elwell-Parker (Limited), of Wolverhampton. This contract has already proved useful; it formed only part of an arrangement with the late Mr. Charles Moseley, of Manchester, which would have been of great importance to the Company, but which could not be fully carried out, in consequence of the untimely death of Mr. Moseley. The Directors are pleased to be able to state that Sir Geo. Elliot, Bart., M.P., who has taken great interest in the Gaulard-Gibbs system for some years past, is likely to join the Board of the Company. The town of Tivoli has been lighted by the Company's system since August in last year, the power used being that of the waterfalls. A contract has been entered into for transporting 2,000 horse-power from the Tivoli Falls to Rome. At the Paris Exhibition of 1886 a "Diplôme d'Honneur" (the highest honour) was awarded to the company's exhibit, which was superintended by Mr. Gaulard in person. The Directors confidently anticipate a great future for the Company, by judiciously meeting the loyal desire generally manifested to recognise the Company's foundation patents. To secure this end they propose to ask moderate royalties, and to supply the most efficient apparatus at prices that remove even the temptation to infringe. The Directors retiring by rotation are Mr. Lucien Gaulard and Mr. J. Dixon Gibbs, who offer themselves for re-election. The auditor, Mr. J. H. Thornton retires, and is eligible for re-election.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 23rd inst. amounted to £4,993.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 23rd December, after deducting the "fifth" of the gross receipts payable to the London-Platino Telegraph Company, were £4,006.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The directors of this company have declared a dividend of 6s. per share for the half-year ending 31st December, 1887, payable 7th January, 1888.

PERSONAL.—Mr. C. E. Wetton, who has been for some years with Messrs. Paterson and Cooper, will, from 1st January next, represent the Telegraph Manufacturing Company (Limited), of Helsby, near Warrington.

COMPANIES' SHARE LIST.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 503.—Vol. XX. FRIDAY, JANUARY 6, 1888. Price 4d.

NOTES.

We are glad to learn that Sir James Anderson will be the Chairman of a Committee of Telegraph Directors and friends who intend shortly to give a Banquet to Sir John Pender, in recognition of his valuable services to Telegraphy, and to congratulate him on the distinction of K.C.M.G. which Her Majesty has been pleased to confer upon him. Mr. William Payton, of Winchester House, 50, Old Broad-street (to whom communications may be addressed), will act as Secretary to the Committee, and Mr. George Draper, of the same address, as Treasurer.

It is quite unnecessary to recapitulate the numerous claims which Sir John Pender has to the gratitude and esteem of all who are connected with Submarine Cable Telegraphy. After the failure of the first Atlantic cable Sir John Pender was one of the foremost amongst the few who still retained their faith in the ultimate success of the gigantic enterprise, and to his personal influence and his liberal financial support the subsequent and successful attempts were mainly due. To his untiring energy and remarkable foresight we also largely owe the success of the Mediterranean, the Eastern, Australasian, and African systems of Cable Telegraphy. In fact the commercial development of the world-wide system which centres in this metropolis—so far as it is due to any one individual—is emphatically due to Sir John Pender. We are therefore justified in believing that the well-merited distinction which he has received will be welcomed with unqualified satisfaction and pleasure throughout the telegraph world.

Mr. Magnus Volk's electric dog-cart, which we describe elsewhere, will prove, we trust, the precursor of a large and miscellaneous family of electric vehicles. This is not, of course, by any means the first attempt which has been made to employ electric locomotion on ordinary roads. To mention only one of the earliest and most successful experiments, it will be remembered that in 1883 Profs. Ayrton and Perry exhibited an electrically-propelled tricycle. Probably, however, Mr. Volk has been well advised to turn his attention at first to a heavier class of vehicle. Although the most advantageous distribution of the dead weight between the vehicle and the cells may, no doubt, be ascertained approximately by calculation, one of the most important points to be considered will naturally be the storage capacity attainable within moderate limits of weight. Now, with a vehicle of the dog-cart type, it would be easy to increase the number of cells when the full load of passengers is not carried, so that with a single rider three or four times as many cells might be employed, and the length of the run proportionately increased.

Mr. Volk's experiment shows conclusively that upon asphalte the coefficient of traction may be taken at less than one half its value upon an ordinary macadamised road. In the next edition of the "Coming Race," or the "Fiftieth Century," we shall probably have a vision of a country where all the roads are paved with asphalte, and everyone travels on his own electric carriage at 40 miles an hour.

Mr. Irish's india-rubber conduit for electric tramways, which we describe elsewhere, seems to offer a promising solution of the difficult problem of electric traction in towns minus storage batteries. The most serious objection to the proposal will probably lie in the expense, for the tubes must necessarily be very thick to ensure the elasticity on which the whole system relies. With india-rubber at 3s. 2d. per pound, and not likely to fall in value, this difficulty will prove, we fear, a serious one. It is nevertheless impossible to overlook the beauty and ingenuity of Mr. Irish's device.

If there is any rubber left after Mr. Irish's wants are fully supplied, Mr. Bozon proposes to employ it to give increased elasticity to overhead wires. We have examined Mr. Bozon's "compressors" with interest, and while it is open to many of the objections which have recently been urged against Mr. Caws's "springs on telegraph wires," we must admit that in some obvious points, as in cost and weight, the india-rubber arrangement is superior to the steel spring. Mr. W. H. Preece has, however, already stated in these columns that, so far as the Post Office is concerned, the necessity for such a device does not exist, and to this it may be added that had such a requirement been manifest, it would doubtless long ago have been designed and employed by the Government telegraph engineers.

On the other hand, in the case of the over-house lines of Telephone Companies, perhaps more especially where these are of copper (for which, according to Mr. Caws, such a device is pre-eminently adapted), and also for overhead electric light

Digitized by Google

circuits, it is at least open to discussion whether something of the kind might not prove advantageous.

THE French Academy is, perhaps, a little unfortunate in its choice of a subject for competition in electrical science. The offer of a gold medal of the value of 3,000fr. has been renewed for several years in succession, so far without result. The subject selected is "The Perfection in some important point of the Theory of the Application of Electricity to the Transmission of Power." Last year one paper only was sent in, but this did not appear to the committee to be of sufficient merit to receive the award. If we may be permitted to offer our own opinion, we would remark that as regards the transmission of power by continuous currents, the theory is already complete in every practical sense of the term, and has been so ever since the laws of efficiency and maximum output were properly understood. On the other hand, the conditions affecting the transmission of power by alternating currents have only quite lately been set forth in detail. The current number of the *Philosophical Magazine* contains a most important contribution to the subject by Mr. T. H. Blakesley, M.A., in a paper entitled "On a Geometrical Determination of the Conditions of Maximum Efficiency in the case of the Transmission of Power by Means of Alternating Electric Currents." This is a further extension of the geometrical treatment of alternating currents first developed by Mr. Blakesley in the columns of this journal in 1885. An equally important paper on the other side of the same question was contributed to the British Association meeting in the present year by Mr. G. Kapp, "On the Condition of Maximum Work Obtainable from a given Source of Alternating Currents." These two papers, therefore, cover between them the whole ground of maximum efficiency and maximum output, and had they been submitted to the Academy it may be taken for granted that either or both would have received the award. It would thus appear that there is very little likelihood, in the present condition of our general knowledge of the subject, that any further development of the theory of the electrical transmission of power will be immediately forthcoming, and it is perhaps unfortunate that the Academy has not propounded for this year some more promising subject.

ALTHOUGH the Grand Theatre at Islington was chiefly lighted by electricity, the cause of the disaster which levelled it to the ground in the early morning of yesterday week was the gas jets in the flies—that is to say, in the most inflammable portion of the structure. The electric current, it is safe to assume, was turned off at the end of the performance, but one or more gas jets were kept burning for purposes of night inspection. Of all places in a theatre this is the one where gas should not be allowed on any pretence whatever, and to keep it burning in such a situation is to court the very consequences the inspection is intended to guard against.

WRITING to *The Times* on this subject, Mr. W. T. MAKINS, who, it may be remembered, witnessed the outbreak of the fire at the Opera Comique last May, makes a very extraordinary statement with reference to the electric light. The main obstacle to its adoption for stage purposes, he alleges, is its unsuitability "on account of the difficulty, if not the impossibility, of partially raising and lowering the light, as required for scenic effects—a drawback which is not shared by gas." We are not aware that a difficulty of the kind referred to has been experienced in any theatre where the electric light is installed; and we are perfectly sure that no competent electrical engineer would admit that any such difficulty exists.

THE Revenue Returns just issued for the year 1887, although on the whole satisfactory, do not point to any marked revival of prosperity during the closing months. The Telegraph Service, which is as good an index to the activity of trade as any we could select, has yielded a gross revenue of £20,000 for the concluding three months in excess of that for the corresponding period of 1886, the figures being £465,000, against £445,000. Comparing the corresponding quarters of the past two years, what we have recently stated with reference to the diminishing increase of the telegraph revenue seems to be borne out, the progressive improvement in the first three quarters of the year being considerably less in 1887 than in 1886; whilst in the concluding quarter—which is always a slack time—of the year just ended, the fall in the receipts has been rather heavier than usual. It is gratifying to note, however, that in the nine months of the present financial year, the total increase on the gross receipts for the Telegraph Service has already reached £85,000.

IN connection with the use of arc lamps for large retail establishments, a very encouraging report has recently come under our notice. A tradesman who is employing the arc light in a drapery establishment in a certain provincial town stated that when the supply was unavoidably discontinued for a short time the difference in his takings amounted to a sum which we take it must have covered the entire cost of lighting for the whole year. In this case many of the neighbouring establishments were also supplied with arcs, and a centre of trade was thus created for the evening customers, so that this quarter of the town has practically monopolised the market. A further remark made was that "the use of the arc light is not with us a mere matter of school-boy preference, but an absolute commercial necessity." In this case it should be added that the lighting is of an unusually excellent description, and the establishments are mostly supplied with arcs outside or in the windows, and incandescents within.

SOME of the specimens of private enterprise in arc lighting with which Londoners are unhappily familiar can only be described as admirable illustrations of how not to do it. If the proprietors could by any means be induced to suppress these nightly displays of chromatic aberration, and return for the time to gaslights, they would confer a distinct boon upon the cause of electric lighting in general. We feel sure that they must already have deterred a large number of persons from the employment of arc lighting.

Digitized by Google

THE fault in most of these cases undoubtedly lies neither with the lamps nor with the machines, but with the quality of the carbons burnt. There are now in the market at least half-a-dozen arc lamps which under suitable conditions may be relied on to burn a really good carbon with a steadiness approaching to perfection; but we have not yet met with a lamp capable of producing satisfactory results with inferior carbons. Nor do we see any likelihood that such a lamp will ever be forthcoming. When the nature of the problem is considered, it is perfectly clear that an infinitesimal variation in the quality or structure of the carbon must make itself unpleasantly manifest in the arc. It is not merely a question of impurity, it is also necessary to insure as nearly as possible an absolute homogeneity of structure. We do not claim that any novel view is presented in this observation, but we do think that the matter may profitably be forced upon the attention of the users of arc lamps.

IT is fortunately true that carbons closely approximating to the above description are to be obtained, but they are naturally more expensive than the inferior varieties. At a central station in the North of England which we have recently visited we were informed that the difference in the cost of supplying the arc lamps with a cheap American carbon instead of a certain make which they were in the habit of using just covered the whole cost of wages for the men employed. But the company nevertheless found it profitable—and, in fact, necessary—to adopt the more expensive article.

THE *Journal of Gas Lighting* is very angry with the Imperial Continental Gas Association for having undertaken the lighting of the Vienna Theatre by electricity, ostensibly because the Association has no right to apply the capital of its shareholders to any business not strictly its own. We are tempted to ask what is strictly the business of, for example, the Gas Light and Coke Company? To sell gas-light and coke? But we know that when paraffin threatened its business the company launched into gas-cooking stoves, to say nothing of gas engines, neither of which is related to cokeing or lighting of any kind whatever. The real ground of the *Journal's* objection, we gather from incidental observations let fall in the course of its moralising is, that if the Vienna experiment should succeed, it will do a good turn to the electric lighting business. "Is it wise," asks our contemporary, "for gas engineers to teach electricians their business?" Certainly not; and it would be still less wise for electricians to learn their business of gas engineers. But it still remains a question whether gas engineers may not study with advantage the business of electric lighting, which, after all, is more strictly in their line than some other businesses in which they have found it expedient to engage.

OWING to Mr. A. E. Kennelly's departure for America he is unable to complete the series of papers entitled "Letters for Learners" which began with the present volume of this journal. We have, however, the pleasure of announcing that the papers will be continued by Mr. H. D. Wilkinson, of the School of Electrical Engineering, Princes-street, Hanover-square. Mr. Wilkinson's first chapter appears in our present issue.

Salford.—The Lever System of Electric Lighting is being installed at the works of Messrs. Smith and Coventry, Salford.

Sir John Pender, K.C.M.G.—Our readers will be gratified to notice that among the New Year Honours the distinction of Knight Commander in the Order of St. Michael and St. George has been conferred upon the Chairman of the Eastern Telegraph Company.

Fleming's Business Diary.—Messrs. Fleming, Son and Co., of Halifax, manufacturers of oak bark-tanned leather belts, &c., send us a copy of their "Practical and Useful Diary for 1888," which publication contains a large amount of information of practical value to business men.

The Bell Telephone Suits in America.—Elisha Gray has applied for leave to amend his original specification in the American Patent Office by inserting the word "metallic" before the word "diaphragm." The Bell Company are opposing the application.

A Substitute for Mercury in Air-Pumps.—Mr. William Crookes has recently pointed out that if gallium could be obtained in sufficient quantity, it would be a perfect metal for producing vacuum in air-pumps, as it is liquid at 86deg. F., gives off no vapour, and does not oxidise.

The John Pender Gold Medal.—The John Pender Gold Medal has been gained by James Raeburn, jun., who is at present an electrician with Messrs. Ganz and Co., Buda-Pesth, as the best electrical engineering student taking the diploma of the Glasgow College of Science and Arts.

Attempted Assassination.—As M. Raynaud, Director of the Paris Telegraph School, was leaving the Ministry of Posts and Telegraphs at noon on Wednesday several revolver shots were fired at him, two of which took effect; but the wounds are not considered dangerous. The would-be assassin was arrested.

Copper-coated Carbons in America.—The Brush Electric Light Company in the United States are bringing an action against the Faraday Carbon Company for infringement of their patent for copper-coated carbons. Several other carbon manufacturers have formed a combination to defend the suit, and a good deal of interest is felt in the result.

Electric Lighting in Regent-street.—Messrs. H. J. Nicoll and Sons, whom we have before mentioned as being amongst the first to adopt the electric light, have recently adopted the "Brockie-Pell" arc lamps, which are supplied direct from a dynamo driven by a gas engine. The remarkable steadiness of these new lamps may be observed by anyone passing the establishment in the evening. A similar installation has also been fitted up at their branch house in Manchester.

Greenwich Time by Telephone.—Those of our readers who are subscribers to the Metropolitan Telephone Exchange will be pleased to hear that Messrs. Barraud and Lunds, of 49, Cornhill, E.C., have contracted with the United Telephone Company for the entire maintenance of their time system in the whole of their exchanges; and will be pleased at any time, and from any subscriber of the United Telephone Company, whether their own customer or not, to answer a "call for time," and transmit an accurate vocal Greenwich mean-time signal. Messrs. Barraud and Lunds' telephone is No. 1155.

Digitized by Google

The Direct United States Company's "Almanack and Calendar."—We have received from the Direct United States Cable Company a "Calendar" for 1888, containing many important and interesting items in connection with submarine telegraphy. The "Calendar" contains the dates of various electrical discoveries since a very early period. The compilation of the "Calendar" must have required a good deal of labour, and we trust the Direct Company will receive the credit due to them for this publication.

Sheffield.—A malicious act was perpetrated at Sheffield on Friday last, when a cable belonging to the Sheffield Electric Light and Power Company was wilfully cut. The cable consisted of seven strands No. 18, and as the ends were clean cut at a place where it could not be reached without a ladder, it is evident that the act was a wilful and malicious one. The wire conveyed a 10-ampere current from a Thomson-Houston dynamo, and it is perhaps unfortunate that the current was not on at the time, or the perpetrator would no doubt have been discovered.

Awards at the Newcastle Exhibition.—The awards at the Newcastle Exhibition have just been made public. The only gold medal in connection with the lighting industry is that awarded to Messrs. Clarke, Chapman, Parsons and Co., for the turbo-electric generator. The recipients of silver medals for electric lighting are Messrs. Paris, Scott and Co., Norwich, dynamo machine; J. H. Holmes and Co., Newcastle, friction gear for dynamo; Dorman and Smith, Manchester, porcelain lamp holders; and Woodhouse and Rawson, London, Scharnweber's diamond arc lamps.

Annual Dinner of the Exchange Telegraph Company's Employes.—The Exchange Telegraph Company's *employés* held their first annual dinner at the Oriental Restaurant, Blackfriars, on New Year's Eve. Mr. F. Higgins (engineer) presided, Mr. W. King (secretary) occupying the vice-chair. The toasts of the evening included "The Directors of the Company," coupled with the health of the managing director, "The Chairman," and "Vice-Chairman." Some capital songs and recitations were rendered by members of the staff, and a most enjoyable evening terminated about 11:30 with "Auld Lang Syne."

The Copper Boom.—A Caution.—Messrs. J. Berger, Spence and Co., in their monthly report on the metal markets, state that they have no certain information as to the future of copper, and recommend great caution. They look to increased supplies by the impetus giving to copper mining, but in the meantime the market is in the hands of the syndicate. Large quantities of copper have been shipped over to France, where there would appear to be no increased outlet for it; and if this large quantity of copper be suddenly re-shipped to this country, a panic must ensue, and be attended by disaster to those outsiders whose tendency is to buy.

The Lighting of the Lyceum Theatre, Edinburgh.—Mr. Geipel writes us from Edinburgh as follows:—"I notice in your last issue you state that the Lyceum Theatre, Edinburgh, was electrically lighted for the first time on the night of the 26th ult. Permit me to inform you that the Anglo American Brush Corporation have lighted the auditorium and entrances to this theatre since May last. You doubtless refer to an extension of this lighting to the stage, which Messrs. Howard and Wyndham recently entrusted to the Brush Corporation, as a result of their great appreciation of the system employed. Messrs. Howard and Wyndham have also placed in the hands of the Brush Corporation a contract for lighting the Royalty Theatre, Glasgow, throughout by their system."

Extension of National Telephone Company's Trunk Lines.—The trunk wire joining the National Telephone Company's Dundee and Kirkcaldy Exchange systems has just been completed and opened for use. The length of the wire, including the cable under the Tay, is fully thirty miles. Kirkcaldy is already connected with Stirling, Alloa, Dunfermline, and other towns in that district, in addition to being in communication (through Stirling) with Glasgow and Edinburgh, each of these being more than 100 miles from Dundee as the wires go. Conversations between Dundee and each of these places were satisfactorily carried on. The completion of the Kirkcaldy trunk wire now enables not only subscribers, but also the general public in Dundee, Perth, Forfar, and Arbroath, on payment of the fee message charges, to communicate with the company's subscribers in Kirkcaldy, Dunfermline, Inverkeithing, Tillicoultry, Alloa, Clackmannan, Stirling, Bridge of Allan, Falkirk, Grangemouth, and Linlithgow. Exchanges are soon to be opened at Markinch, Leven, Cupar, &c., and these will also be in connection.

Cheltenham Street Lighting.—At a meeting of the Corporation of Cheltenham, held on Monday last, Mr. Councillor Norman proposed a resolution instructing the Streets and Highway Committee, as the committee having charge of the public lighting of the town, to report on the advisability and the practicability of introducing the electric light for public purposes in Cheltenham. In the course of a lengthy speech Mr. Norman adduced a mass of information collected from several Continental and English towns to show that electric lighting was preferable to gas lighting, on the ground that it is a better light, a healthier light, and, under certain conditions, might be made a cheaper light.—Mr. Waghorn seconded the motion, and in the course of the discussion which ensued no opposition was raised to the principle of the reference, though Mr. Lawrence desired the reference to be made to a special committee.—Ultimately it was decided to adjourn the subject till the next monthly meeting, when Mr. Lawrence will move that the words "Streets and Highways Committee" be struck out of the resolution and the following inserted instead:—"A special committee of the council, with power to call in skilled assistance if required."

Nickel Plating.—According to the *Bulletin Internationale de l'Electricité*, the following solution is employed for nickel plating by several firms in Hainault. It is said to give a thick coating of nickel firmly and rapidly deposited. The composition of the bath is as follows:—

Sulphate of nickel	1lb.
Neutral tartrate of ammonia	11·6oz.
Tannic acid with ether	·08oz.
Water	16 pints.

The neutral tartrate of ammonia is obtained by saturating tartaric acid solution with ammonia. The nickel sulphate to be added must be carefully neutralised. This having been done, the whole is dissolved in rather more than three pints of water, and boiled for about a quarter of an hour. Sufficient water is then added to make about sixteen pints of solution, and the whole is finally filtered. The deposit obtained is said to be white, soft, and homogeneous. It has no roughness of surface, and will not scale off, provided the plates have been thoroughly cleaned. By this method good nickel deposits can be obtained on either the rough or prepared casting, and at a net cost which, we are told, barely exceeds that of copper plating.

Electric Lighting in Theatres. — The views of several theatrical managers on the subject of electric lighting are set

Digitized by Google

forth by a writer in the *Echo* as follows. It will be seen that they are of a somewhat divergent character:—"A manager who uses it not in his theatre, but in a large restaurant, and who is now preparing to put it into his theatre, says:—'In any place where more than £1,000 a year is paid for gas, electricity is cheaper. It is just as certain, too, as gas. I have had no mishap whatever with it for two years. Besides, any sudden failure can be provided against by having every chandelier or row of lights supplied by two different sets of wires coming from two different dynamos. Next, there is absolute safety. It is nonsense to talk of danger from the wires; they are as cold as ice, and there can be no fire from them, as now arranged. Again, in the matter of assurance there will be tremendous gain. Some theatres in London cannot be insured at all. Many pay as much as from £2 to £3 per cent. per annum, which on, say, an insurance of £20,000 is a heavy charge. It could be reduced to a very small sum indeed were there no gas in the theatre. My feeling is in favour of electricity, and that alone, and I mean to adopt it. Manager No. 2 said: I find that although I have electricity in my theatre I cannot do without gas. To say nothing of the chance of its going out, electricity will not warm a house, and I have had to light my gas two or three times this winter because the place was too cold without it. In the case of a new theatre this is especially noticeable, and it must be provided against. I know you will say that hot water could be used. But I do not think that there is less danger in having a big heating apparatus under a theatre than in having gas in the house only for use on emergency, or to warm the building. I question very much if the fire at the Grand was occasioned by gas. Manager No. 3 said:—Until electricity is in a much more perfect state than at present, it will be useless for big spectacular scenes, such as in pantomimes for instance. We must have gas, and we shall have to use it. But we may take all proper precautions, and it is our interest to do so. Gas for the present is a necessity."

The Durability of Gutta Percha.—Mr. H. A. Reed writes to the *Electrical Review* of New York on the above subject as follows:—"In 1849 the Merchants' Telegraph Company built a line between New York and Boston to work the Bain system. They expected to cross the Harlem River on High Bridge, but being unable to get permission to attach the wire to the bridge, Mr. Charles T. Smith, who had charge of building the line, had a No. 9 black iron wire covered with gutta percha by Mr. Samuel T. Armstrong, of Brooklyn, who was the first man to introduce gutta percha into this country, and who at that time was using large quantities of it in making pipes for water, acids, &c., and in lining tanks for various purposes. The wire was covered and laid under the supervision of Mr. W. W. Marks, the present superintendent of the Bishop Gutta Percha Company. It worked for several years, but was afterwards superseded by a more modern cable, and was forgotten until the spring of 1879, when some labourers at work near High Bridge struck with their spades something which seemed rather tough for a root, which they at first thought it to be, but on further examination found it a wire covered with gutta percha. A long piece of the wire was obtained by Mr. Marks, and although it had been buried for thirty years, the gutta percha insulation was still in good condition. I notice in this week's *Review* that the Atlantic cable, which was laid in 1869, though showing the effects of time—probably by the corrosion of its armour—is still working well. We have at our office a piece of gutta percha pipe which was laid under the East River in 1848, to convey water to Blackwell's Island, and was taken up in 1885. The gutta percha was in good condition, and was brought back at about one-half the cost of new gum, we realising a good profit on the transaction. In 1873, Mr. Marks made a 10-conductor cable, which was laid under the Capitol grounds at Washington, being buried in a trench with no protection except a wrapping of tarred tape. About three years ago the cable, which was still working, was cut in making some excavations, and Mr. G. C. Maynard, who repaired it, sent us a sample to show that the cable was then as good as new. Another 'proof of the pudding by eating' is that we and others pay 40 cents per pound for the gutta percha stripped from the cores of Western Union cables, after they have been used long enough to completely destroy the armour. This material is not used a second time for insulation, but answers well for some other purposes."

Lectures on Electricity by a Lady for Ladies.—A course of six elementary lectures on electricity will be given by Mrs. Ayrton at 2, Upper Phillimore-gardens, W., on January 17th, and the five following Tuesdays, at 5:15 p.m. The course, which will be fully illustrated by experiments, will be strictly elementary, and will pre-suppose no scientific nor mathematical knowledge. Tickets for the course may be obtained by letter from Mrs. Hancock, hon. sec., 125, Queen's-gate, S.W., to whom application should be made before January 13th. Single tickets £1. 1s.; to admit six £4. 4s. The following is the syllabus:—January 17th, What Electricity can do for us.—(1.) In our households—Lighting, ringing bells, winding clocks, working machines, such as sewing, boot cleaning and plate cleaning machines, telephony. (2.) Out of doors—Lighting large spaces, fire alarms, driving tricycles, cabs, tramcars, trains, launches, transporting goods. (3.) In our manufactories—Electro-plating, electro-typing, purifying metals. January 24, The Different Ways of Obtaining a Supply of Electricity.—Electricity among the Greeks; Galvani and Volta's discovery of the electric current; galvanic batteries; energy—its different forms; the conservation of energy; the purposes for which galvanic batteries are economical—bells, signals. January 31st, Faraday's discovery.—How to Produce Large Currents.—Electric pressure or potential. The difference between a good conductor, such as copper, and an insulator such as gutta percha; importance of good insulation to prevent accidents and waste; lighting of Grosvenor Gallery, St. James's Hall, &c., by the Grosvenor Gallery Electric Supply Association; the distance through which large currents can be sent; Deprez's installation 37 miles; the storage of electric energy. February 7th, Electric Lighting for Houses.—Incandescent lamps, how they are made; the cost of lighting (1) a dinner table, (2) a ball room, (3) a house with incandescent lamps for one evening; the cost of lighting a house permanently with incandescent lamps; the Electric Lighting Act, how it has impeded the use of electricity in England. February 14th, the Physiological Effects of Electricity.—Galvani's experiment with the frog; need for scientific precision in the application of electricity to the cure of disease; an electric hospital; why lightning is dangerous; why trees should be avoided in a thunderstorm; lightning conductors worse than useless unless properly constructed; points to observe when they are put up. February 21st, Transmitting Messages, Music, and Song by means of Electricity.—The telegraph; submarine cables; the telephone; the microphone, or sound magnifier; the phonograph; seeing by electricity—can it be accomplished? the future of electricity. We may add that Mrs. Ayrton is a graduate of Girton College, Cambridge, has been a pupil at the City and Guilds of London Finsbury Technical College, and is now a pupil at the Central Institution.

SOME ENGLISH CENTRAL LIGHTING STATIONS.

II.—BRADFORD.

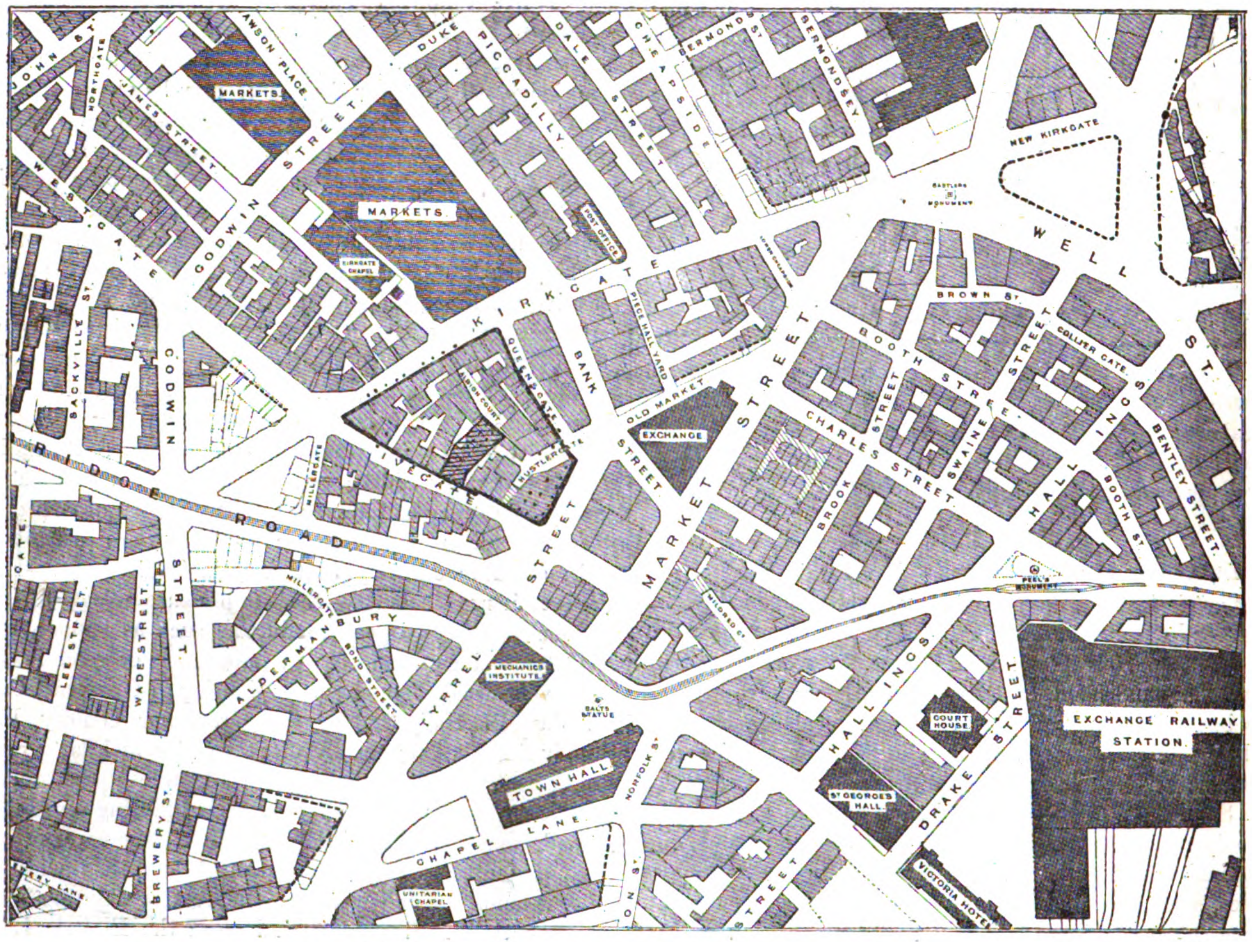
It is not our present intention to make any further reference to the negotiations between the Corporation of Bradford and the local company which is already engaged in the business of central station lighting in that town; but having recently paid a visit to the works of Messrs. Schmidt-Douglas and Co., we propose to give a brief account of the station and of the facts connected therewith which have come under our notice. We may, however, remark at the outset that we have been very favourably impressed with the character of the work, which we cannot but regard as one of the finest specimens of electrical engineering at the present time to be found in this country. The excellence of the arc-lighting is especially noticeable, nothing finer having at any time come under our notice. The only subject for regret in this connection arises from the fact that the dynamos, lamps, and carbons are all of foreign manufacture.

they erected two high-pressure quick-speed engines to drive two compound dynamos yielding current for about 150 incandescent lamps and 20 arc lamps.

This installation having proved a success, both consumer and supplier being perfectly satisfied with the results, it was decided during the summer of 1887 to alter the works for the purpose of erecting a central electric lighting station on an extensive scale.

Application was therefore made to the Corporation with a view of obtaining permission to carry the wires either over or under the adjacent streets. The company were prepared to pay a royalty upon each lamp so supplied in recognition of the powers held by the Corporation; but the negotiations ultimately fell through, the parties being unable to come to terms.

Messrs. Schmidt-Douglas, wisely or unwisely, nevertheless determined to proceed with their preparations for undertaking the supply of current upon an extended scale, and their plans were laid out under the expectation of ultimately developing about 5,000 horse-power. The old buildings, occupying an area



PLAN OF CENTRAL DISTRICT OF BRADFORD

Showing the area lit by the Schmidt-Douglas Company. The works will be seen between Ivegate and Albion Court. The dots represent arc lamps.

The adjoining plan represents the central portion of the town of Bradford, and it will be seen from this that the station is situated in the heart of the town; the town hall and municipal offices, the Exchange, Railway Station, extensive markets, principal clubs, and other public buildings all lie within a narrow circle, of which the station is approximately the centre. The most important retail shops are also in the immediate neighbourhood, so that if the supply were restricted to a low-tension direct-current distribution, it would be impossible to select a more favourable situation.

The commencement of the work dates back only to the summer of 1886, when Messrs. Schmidt-Douglas and Co. commenced to supply the electric current for lighting purposes to a few shops and to some of their friends having places of business round about their works at Hustlergate. For this supply

of 750 square yards, were partially removed, and the foundations were laid of a substantial structure suited for the employment of heavy machinery on the upper floors. The bottom floor, intended for the engine room, rests on the solid rock. The boilers were to be on the street level, and the dynamos on the first and second floor above. A sectional elevation of the building is shown in Fig. 2.

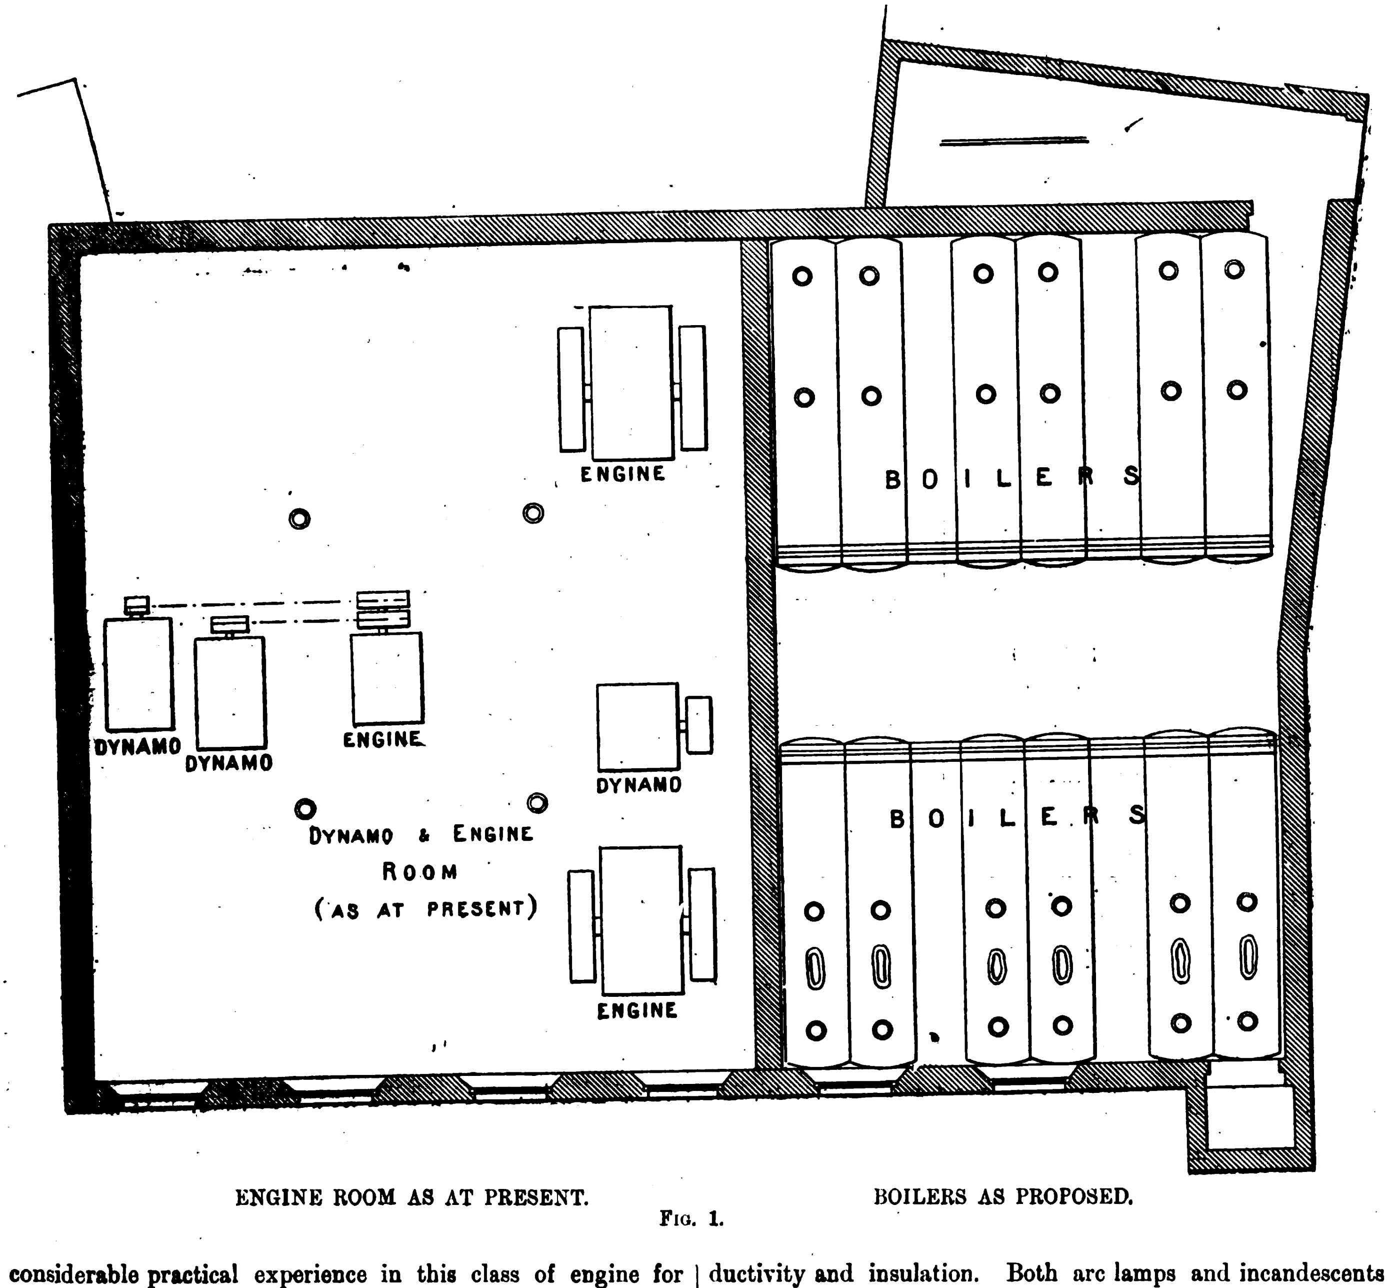
The building is constructed of compound steel girders composed of two 7in. by 9in. single girders and riveted together top and bottom with ⅜in. steel plate. These girders run the whole width of the building, and are supported by iron pillars 10ft. high, the end pillars being walled in. Between each length of girder are filled cross girders 4in. by 7in., 2ft. apart, and between each of these cross girders are double-brick arches. All the floors are concreted, forming one solid

Digitized by Google

fireproof mass of building in every way suitable for the erection of heavy machinery.

Great consideration has been given to the production of steam by the most modern and economical means at command, and the smoke from the furnace is entirely consumed. Only one boiler has yet been brought into use, although two are in position. They were supplied by the Babcock and Wilcox Company, and are on the high-pressure system, steam being taken from the boilers between 100 and 150lbs. pressure. The boilers are set to blow off at 200lb., and are supplied with water from the town mains, by Worthington's high-pressure steam rams, and also by exhaust injection, either source of supply being employed at will. The engines have been specially constructed by Messrs. Browett and Lindley, who have had considerable practical experience in this class of engine for electric lighting. Three engines are at present in position, of which one is spare. The engines are vertical, side-by-side compound, being fitted with Lindley's high-speed governors. Messrs. Schmidt-Douglas speak very highly of this governor, which they find to be very reliable and efficient, governing well with a steady or variable load. The engines are fitted with automatic oiling arrangements. Two dynamos are at work with one spare machine; they are by Schuckert, of Nuremberg, and were specially built for this station, and are compound-wound. At the time of our visit the machines were running very cool, and were entirely free from sparking. Each machine is fitted with a Schmidt-Douglas bulb-drop, sight-feed lubricator, and also with a Schuckert voltmeter and pilot lamp. The dynamos are at present fixed in the same room as the engines, the arrangement being as shown in Fig. 1. Each machine is driven by a 12in. leviathan belt, specially constructed by Hebblethwait Bros., of Huddersfield. We were informed that these belts have given great satisfaction. Each dynamo is fixed on timber foundations, securely bolted to the floors, and care has been taken that the machines shall be thoroughly insulated from the ground. Belt tightening gear is fixed to each dynamo. At present the total production of current amounts to 1,000 amperes at 110 volts.

The cables used are of high quality both as regards conductivity and insulation. Both arc lamps and incandescents are run on the same circuit, the arcs being connected two in series across the parallel.



ENGINE ROOM AS AT PRESENT. BOILERS AS PROPOSED.

Fig. 1.

The wiring of the consumers' premises has evidently been carried out with great care, the Phœnix Fire Office rules being observed in every respect. The arc lamps are also by Schuckert, and although as regards steadiness and colour we have occasionally seen an equally good performance elsewhere, we are bound to admit that we have never at any time seen anything better. The excellence of the result attained is due in large measure to the quality of the carbons consumed, which are of German manufacture.

Digitized by Google

The tariff charged by the company is at the average rate of £1 per month for arcs and 4s. per month for incandescent lamps, but depends upon the number of lamps supplied. No other charges are made, and the fittings are supplied and fixed by the company. The number of lamps in use at the present time is about 60 arcs and 200 incandescents, and very nearly the whole of the block which can be reached without crossing the streets has already been supplied.

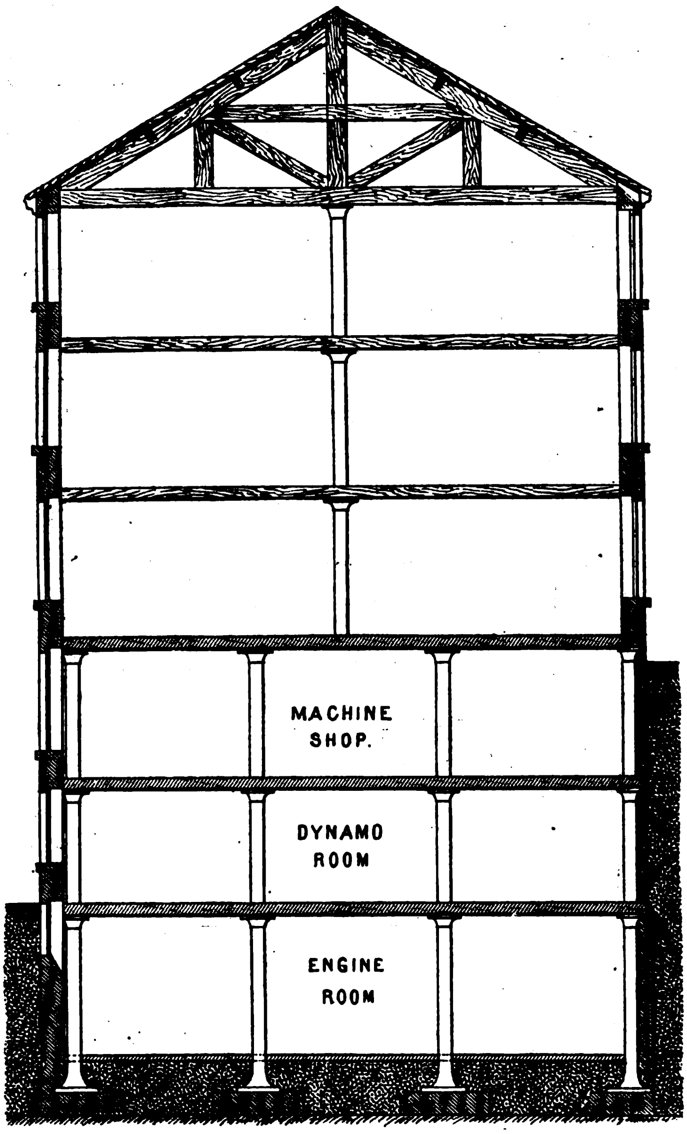


Fig. 2.—Section of building as proposed. The first three floors only are at present built.

Taken as a whole the installation does very great credit to the engineers of the company, and its inspection will well repay a visit to Bradford.

PORTABLE VOLTMETERS FOR MEASURING ALTERNATING POTENTIAL DIFFERENCES.

BY W. E. AYRTON AND JOHN PERRY.

It is now well understood that a high-resistance electrodynamometer cannot generally be used for measuring alternating potential differences, in consequence of the self-induction of the dynamometer causing the effective resistance—and therefore the sensibility—of the dynamometer to vary with the speed of alternation. Further, even for the measurement of direct potential differences an ordinary high-resistance voltmeter, employing the magnetic property of the current, is not entirely satisfactory if the forces employed be large (as they generally have to be in dead-beat portable instruments), since, in that case, the current, if kept continuously on, slowly heats the voltmeter, and by increasing its resistance causes its sensibility to diminish. It has, therefore, for some time seemed clear that the heating effect of a current should be used for voltmeters.

Captain Cardew was the first person to utilise this principle in the construction of voltmeters, and, as far as we are aware, is the only person who, up to the present time, has employed the extension of a wire caused by the heating produced by the passage of a current to measure the potential difference at its terminals. His instruments are well known, and have afforded most valuable aid in the measurement of alternating potential differences; and we, in common with other electrical engineers, owe him a debt of gratitude for providing us with the only commercial instrument that has existed for the measurement of alternating potential differences.

In "Practical Electricity" an attempt has been made to impartially sum up the advantages and disadvantages of all the more important ammeters and voltmeters, and we cannot do better than repeat what was there said about the Cardew voltmeter, especially as we understand that Captain Cardew considers the criticism to be a fair one.

"CARDEW VOLTMETER.

"*Advantages.*—First, it has but a small heating error; second, the self-induction is negligible. It is also dead beat, direct-reading, not disturbed by magnets, and fairly portable, although large.

"*Disadvantages.*—It absorbs a good deal of energy; second, it cannot be used for measuring a small potential difference, for we cannot make it of thicker wire, as we should do in the case of an ordinary voltmeter intended to measure small potential differences, as this would render it sluggish, since a thick wire traversed by a current heats and cools slowly on starting and stopping the current; third, there is considerable vagueness in the readings near the zero point, and sometimes inaccuracy in the upper parts of the scale."

Towards the end of 1885 we were engaged on certain experiments on the governing of transformers in series to give a constant potential difference at each house, and, as our experiments were to be conducted with small transformers, we required a voltmeter which would measure an alternating potential difference of three or four volts with accuracy. Such an instrument not being in the market, we were compelled to devise one, and we were led to consider whether the Cardew principle might not be employed in an instrument which should give quite definite readings even near the zero, and produce a large deflection when an alternating potential difference of a few volts was maintained between its terminals.

Part of the vagueness in the readings of the Cardew instrument we saw was due to the employment of toothed wheels; and, as explained in a paper* read by us before the Royal Society in 1884, toothed wheels have not recommended themselves to us as a means of magnification in ammeters and voltmeters, in consequence of the friction they are liable to introduce. In fact, after giving toothed gearing an extensive trial in our instruments, originally described to this Society† in 1882, we decided to abandon its use in 1884.

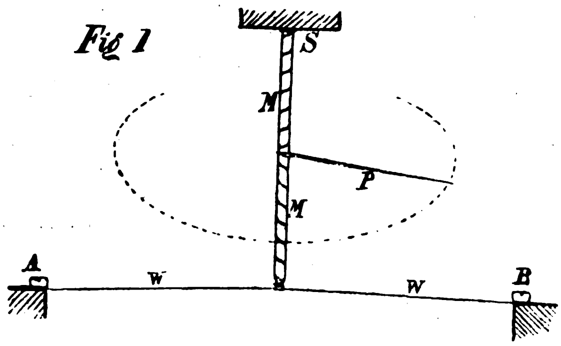
If a voltmeter depending for its action on the expansion of a wire by heating is to be sharp in its action, the wire must be fine; and if it is to measure a small potential difference the wire must be short; hence we were led to consider whether it was not possible to construct a voltmeter of quite a short length of fine wire, and observe its extension with some frictionless magnifying arrangement. This led us to consider the platinum wire telephone described by Mr. Preece in his paper‡ read before the Royal Society in 1880, which, although composed of but a short length of wire, evidenced by the motion of the diaphragm, to the centre of which one end of the wire was attached, every change in the current passing through it. After thinking out various means of attaining this result, we

* "A New Form of Spring for Electric and other Measuring Instruments."
† "Measuring Instruments used in Electric Lighting and Transmission of Power."
‡ "Thermal Effects of Electric Currents."

Digitized by Google

were led to see that one of our magnifying springs, described to this society in 1882, furnished the means of obtaining a sufficiently sensitive frictionless magnifying arrangement. For experiment shows that if a short piece of fine wire W W (Fig. 1) only seven inches long be stretched between two sup-

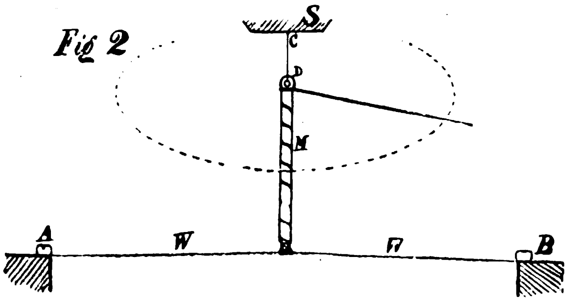
Fig 1



ports A and B to which it is *rigidly* attached, and if it be pulled slightly out of the straight line by one of our right and left handed magnifying springs M, *rigidly* attached at its one end to the wire and at the other to a support S, the axes of the spring and the wire being at right angles to one another, the arrangement is so delicate that the expansion produced by even the approach of a warm hand is evidenced by the rotation of a pointer P attached to the centre of the right and left handed magnifying spring. The absence of all gearing and the rigid fastening of both ends of the spring, combined with the fineness of the wire, make the arrangement remarkably dead-beat in its action; and when the wire is enclosed in a short metal tube we have a voltmeter which will measure even the fraction of a volt, whether the potential difference be direct or alternating, since the readings even near the zero are quite definite.

The right and left-handed spring was employed to avoid any twist being given to the wire; but one of our assistants, Mr. Bourne, who has worked at this instrument with his customary ingenuity and dexterity, soon found out that half the length of the spring could be dispensed with, and an equally efficient but much more compact arrangement could be effected by using a single ordinary magnifying spring M (Fig. 2), and

Fig 2



introducing a small piece of fine wire C D between the one end of the spring and the stretched wire W W, or between the other end of the spring and the support S.

To get extreme quickness of action on changing the potential difference, it is desirable to employ a thin wire; and as the strength of such a wire is small, the next step was to combine a number of wires mechanically in parallel, and electrically in series or parallel, the wires being attached at their middles to a stirrup which is carried by the magnifying spring; and voltmeters containing as many as twelve short wires, each about seven inches long, were made in the early part of the summer of 1886.

These instruments showed, however, the sluggishness which is familiar to the users of the Cardew voltmeter, and we had to set ourselves to investigate it. Stationary metallic screens were inserted between the wires to assist the cooling, and various other means tried without success, when we set Mr. Bourne to investigate the general question of sluggishness. A variety of experiments were made by him on the rate of variation of the permanent state of a wire with the variation of potential difference at its terminals, as affected by varying the proximity of the wires, their length, &c. This occupied him several weeks, and the experiments he made were too numerous to be recorded here. With our many-wire voltmeter the sluggishness was certainly not due to mechanical friction, as our magnifying spring is practically frictionless; and we gradually saw that the peculiar creeping back in the deflection of a Cardew voltmeter when a perfectly constant potential difference was first set up between the terminals was due to the fact that the draught of air created in the tube by the heated wires takes an appreciable time to be produced, so that the wires are hotter directly the potential difference is applied than they become when the draught begins to flow. A number of more or less successful devices were tried for overcoming this defect—for instance, even the employment of a draught independently maintained—when we found in the summer of last year that the simple device of placing the tube horizontal instead of vertical, and using very fine wire—not much exceeding one-thousandth of an inch in thickness—overcame all the difficulty. The importance of placing the tube horizontal was also subsequently seen by Mr. G. S. Ram this year, and consequently the scales of the Cardew voltmeters are now marked so that the zero is at the top when the tube is placed horizontal.

Fig 3

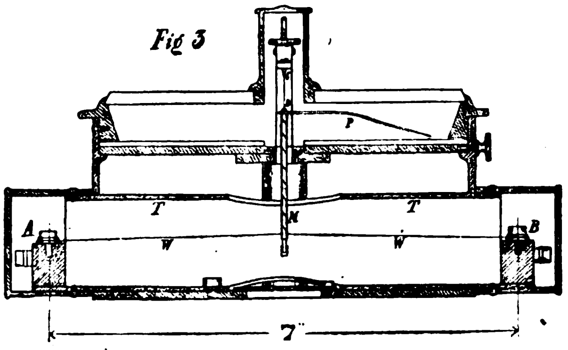


Fig 4

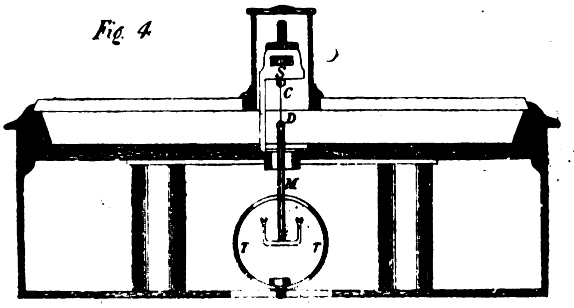


This home-made instrument with two wires lying on the table was then completed in August of last year, and was found to be remarkably sharp and decisive in its action—to give a deflection of 300deg. with 14·22 volts maintained at its terminals. Even a fraction of a volt can be measured with it, as the readings are quite definite even near the zero.

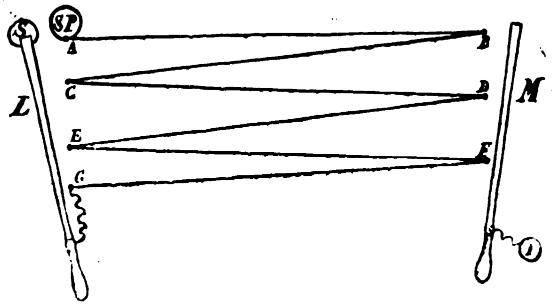
The finest wire employed by Captain Cardew in his commercial instrument has a diameter of 0·0025 of an inch; but, in consequence of our magnifying gearing being frictionless and comparatively massless, we are able to use much finer wire—not more than 0·0014 of an inch in diameter—without any fear of injury, even if the instrument receive a sharp knock. This greater fineness of the wire gives us three times as much resistance per foot, and therefore enables the instrument to be very much smaller; also, as the ratio of surface to sectional area is far greater, the heating and cooling is far more rapid—that is, the instrument is much more dead-beat.

Figs. 3 and 4 show two sections at right angles to one another through the centre of this other two-wire voltmeter which is lying on the table. It has been constructed on the

Digitized by Google

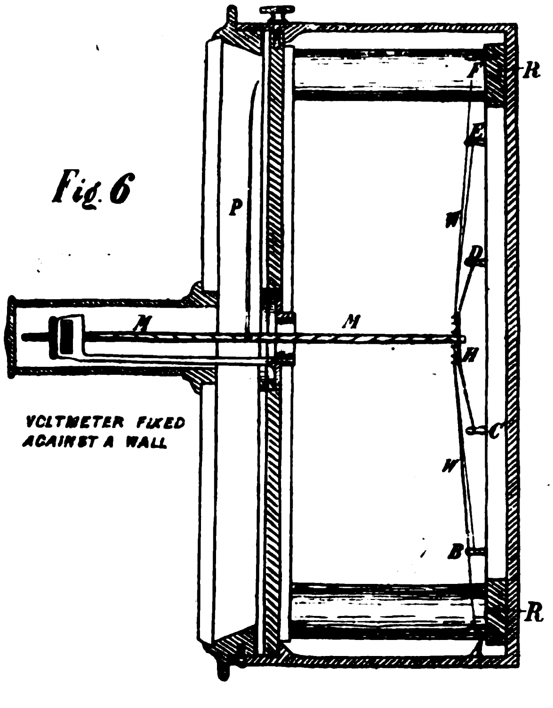
lines of the original one, but in a more workmanlike manner. It is direct-reading, and measures from 0 to 10 volts, the deflection for that potential difference being some 250deg. The same letters are employed to designate the various parts of the instrument as were used in Figs. 1 and 2, with the addition of T, the metal tube surrounding the wires; and the stirrup connecting the end of the magnifying spring with the wires is also shown.

Fig 5



The employment of several short parallel wires soon suggested the addition of the commutator described in our paper read before this society in 1881, for varying the sensibility of a voltmeter. But whereas with our commutator ammeters and voltmeters in which the magnetic action of a current in deflecting a magnetised needle was employed the current had to flow through every wire in the same direction, whether the wires were joined in series or in parallel, with this new form of voltmeter in which the heating property is employed it is

Fig 6

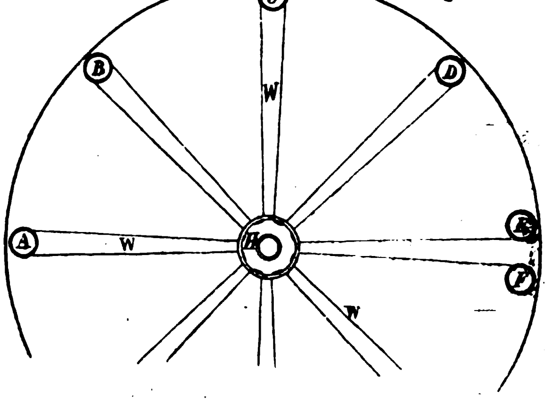


unimportant which way the current passes through a wire. Hence the pins in the barrel of our old commutator which gave trouble may be entirely dispensed with, and the commutator assumes a very simple form. In fact, if A B, B C, C D, D E, F G (Fig. 5), represent wires joined in series in the new form of voltmeter, the series connections need not be disturbed when a parallel arrangement is required, since all that need be done to join them in parallel is to connect the points A, C, E, G, by means of the bar L, and B, D, F, by means of the bar M. S and S P are the terminals for series and P and S P for parallel, so that if the commutator be accidentally turned from series to parallel the circuit is broken and the wires are not fused. This instrument lying on the table is a four-wire voltmeter, and the sensibility is such that 15·2 volts gives a deflection of 39deg. when the commutator is turned to series, and 295deg. when it is turned to parallel.

It is important to notice that the employment of this commutating device to vary the sensibility enables all the wire in the instrument to be always operative in deflecting the pointer; whereas, if the ordinary device of adding an outside resistance coil be employed to enable the voltmeter to measure a larger number of volts, the energy spent in heating this outside resistance coil is entirely wasted as far as deflecting the pointer is concerned; in fact, the greater the outside resistance, the more inefficient becomes the voltmeter.

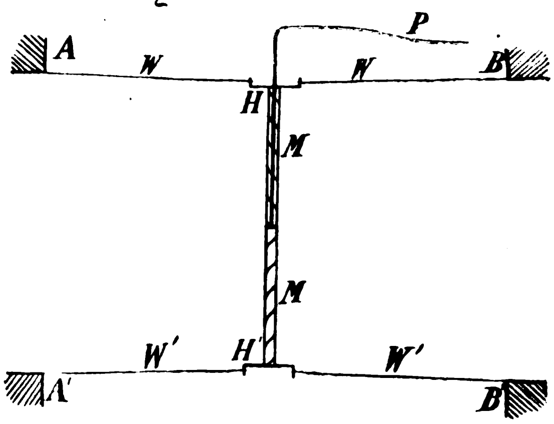
For the object of still more completely carrying out the principle of employing a number of short wires we have also made voltmeters in the following way:—The wires are arranged like the spokes of a small bicycle wheel W W

Fig 7



(Fig. 6); that is, we have a circular rim of a wheel, R, which may be of the same metal of which the wires are made, to eliminate errors due to change of temperature, fitted with non-conducting studs A, B, C, D, &c., to which the wires are attached. There is also a small non-conducting central piece, H, corresponding with the hub of a wheel, to which the wires are also attached; and as the wires come from rim to middle backwards and forwards several times, the arrangement

Fig 8.



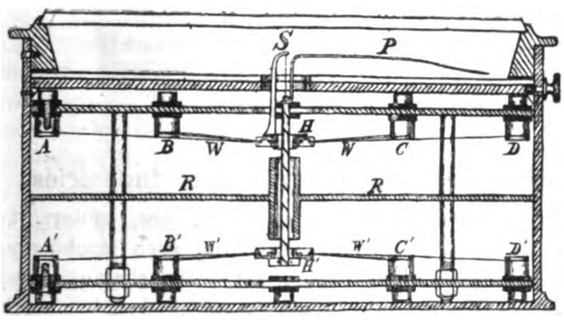
appears like a bicycle wheel with many spokes, as seen in Fig. 7. One end of a right and left handed magnifying spring M (Fig. 6) under tension is rigidly attached to the hub H, and its other end to the support S. Hence, as the wires expand on heating, the spring draws the hub H more out of the plane of the rim, and the rotation of the pointer P measures the current. R is a metallic plate put between the two bicycle wheels to assist in the cooling. This instrument on the table is made exactly in this way. Using two of its three terminals the range is from 0 to 50 volts; or using one of the previous ones and the third, it is from 0 to 100 volts. In both cases, however, the whole of the wire is operative in deflecting the pointer.

Fig. 8 shows a voltmeter made with two bicycle wheels.

Digitized by Google

The letters attached to one of them refer to the same parts as the letters used in Fig. 6, while similar accented letters are used for the similar parts of the second bicycle wheel. As before, one end of the right and left handed magnifying spring is attached to the hub of one of the wheels, but instead of the other end being rigidly attached to the case of the instrument it is attached to the hub of the other wheel. Hence the rotation of the pointer is produced by the expansion of all the wires on both wheels. Fig. 9 shows the actual arrangement of the double bicycle-wheel voltmeter on the table, where an ordinary (not a right and left handed) magnifying spring M is employed, with a flexible connection of fine wire carried by the support S, which itself is carried by the hub H of one of the wheels. The wires are electrically divided into four sets. When the commutator is turned to series, 80 volts produces a deflection of 300deg.; whereas 20 volts produce a deflection of 300deg. when the commutator is turned to parallel.

Fig 9.



In Fig. 6 of the single bicycle-wheel voltmeter the instrument is shown with the dial vertical. But any one of the forms described in this paper may also be used with the dial either horizontal or vertical.

(To be continued.)

ELECTRIC TRACTION CALCULATIONS.

The following table will be found very useful in making calculations connected with electric (or other) traction :—

TABLE

Giving Miles per Hour, in Feet per Minute and per Second.

Miles per Hour.	Feet per Minute.	Feet per Second.	Miles per Hour.	Feet per Minute.	Feet per Second.
1	88	1·46	16	1,408	23·47
2	176	2·93	17	1,496	24·93
3	264	4·4	18	1,584	26·4
4	352	5·87	19	1,672	27·86
5	440	7·33	20	1,760	29·33
6	548	8 8	21	1,848	30·8
7	616	10·26	22	1,936	32·26
8	704	11·73	23	2 024	33·72
9	792	13·2	24	2,112	35·2
10	880	14·67	25	2,200	36·67
11	968	16·13	26	2,288	38·14
12	1,056	17·6	27	2,376	39·6
13	1,144	19·07	28	2,464	41·04
14	1,232	20·52	29	2,552	42·50
15	1,320	22·	30	2,640	44·0

Formula for calculating the horse-power required to propel any vehicle—

$$\text{H.-P.} = \frac{W K S}{33000} \pm \frac{W\,2240\,S}{33000} \sin\theta.$$

where W = total rolling load in tons,
K = resistance to motion expressed in lbs. per ton,
S = speed required in feet per min.,
θ = the inclination of the grade.

The value of S corresponding to any number of miles per hour can be filled in from the table. K can only be determined by experiment, but approximate values can be found in the usual text books. For raised rails K varies from 12·5lbs. to 20lbs.; for sunk rails, from 28lbs. to 56lbs. will be fair limits under ordinary working conditions. On inspection, it will be seen that the first fraction in the equation gives the horse-power required to overcome the resistance to traction on the level only, while the right hand quantity is a measure of the work done either against or by gravity; hence the double sign. The term will be negative on a down-grade, and positive on an up-grade. If the *gravity* term exceed the *traction* term and have a negative sign, the equation becomes negative. This means that the car will travel by the aid of gravity alone. The use of the table and formula will be best seen from an example :—

Let K = 30, W = 8 tons.
Speed = 10 miles per hour,
$\therefore$ S = 880.

And, let $\sin\theta = \frac{1}{50}$;
or, $\theta = 1^\circ\ 9'$.

Suppose the gradient is against the load, we have

$$\text{H.-P.} = \frac{8 \times 30 \times 880}{33000} + \frac{8 \times 2240 \times 880 \times 1}{33000 \times 50}$$

$$= 6{\cdot}4 + 9{\cdot}5 = 15{\cdot}9.$$

A. T. SNELL.

MEETINGS OF SCIENTIFIC SOCIETIES.

(Week ending Thursday, 12th January.)

SATURDAY, January 7th.

ROYAL INSTITUTION.

3 p.m. The last of the Series of Six Lectures on Astronomy. By Sir ROBERT STAWELL BALL, LL D., F.R.S.

MONDAY, January 9th.

INVENTORS' INSTITUTE.

8 p.m. Ordinary Meeting.

TUESDAY, January 10th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Paper, "The Use and Testing of Open-Hearth Steel for Boiler Making." By the late HAMILTON GOODALL, A.M.I.C.E. And Monthly Ballot for Members.

WEDNESDAY, January 11th.

SOCIETY OF ARTS.

7 p.m. Juvenile Lecture II. "The Application of Electricity to Lighting and Working." By Mr. W. H. PREECE, F.R.S.

THURSDAY, January 12th.

THE ROYAL SOCIETY.

4:30 p.m. Ordinary Meeting.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

8 p.m. Presidential Address by Mr. EDWARD GRAVES.

1887.

The Electric Light and Power Industries.

In the construction of dynamo machines, motors, transformers, and the practical application of such machinery, the year 1887 gave birth to no very remarkable novelties. As a matter of fact, the manufacture of dynamo machines has already settled down into the lines of a well-established business, and the leading firms have therefore no reason to abandon types which have secured the favour of users for new and more or less fanciful shapes. Generally speaking, the present tendency is, and has been for more than a year, to adopt the single horseshoe field-magnet, and firms like Messrs. SIEMENS and Messrs. ELWELL-PARKER, who originally made double horseshoe machines, have adopted the single horseshoe field almost exclusively for continuous-current dynamos. Messrs. CROMPTON adhere, however, still to the double horseshoe field for large dynamos, and Messrs. MATHER AND PLATT have retained their "Manchester" type, which is also of the double horseshoe pattern. It is generally admitted that a single horseshoe magnet requires less exciting wire and a smaller expenditure of energy to produce a given field than one of the double horse-shoe form; but the latter, especially when of the "Manchester" type, has the advantage of small weight, cheapness of construction, great simplicity, and solidity. Taking electrical and mechanical advantages into consideration, they appear to be pretty equally balanced between the two designs. When, however, high efficiency is of greater importance than low cost, the single horseshoe machine is evidently preferable. As regards the material for field-magnets, it is curious to note that in some instances cast iron has been reverted to during the past year. In the early days of heavy electrical engineering cast iron was employed either for magnet cores or for pole-pieces in many of the dynamos which then were most in favour. Thus the Weston, Hochhausen, Bürgin and other machines had cast-iron magnets. When the laws of the dynamo began to be better understood, and when it was recognised that by the employment of wrought-iron magnets of the same size the electromotive force of the machine could be increased by about 40 per cent., this material was at once adopted, and cast-iron magnets were considered a thing of the past. But in this sudden reversion to the more expensive material the makers

Digitized by Google

overlooked the fact that cast-iron magnets could be made just as efficient as wrought-iron ones, provided the sectional area be sufficiently increased. Now, an increase of sectional area means an increase in the length of the convolutions of the existing coils and an increase in weight. These are undoubtedly disadvantages, but, on the other hand, some saving can be effected in labour and in the prime cost of the magnets, besides the advantage of a machine containing fewer parts. Whether these advantages are sufficient to make up for the disadvantages of cast-iron magnets depends on the relative price of cast and wrought iron, on the cost of labour, on the price of copper, and on some local circumstances. With copper at its present price, and when well annealed magnet forgings can be had for something like 16s. or 17s. per cwt., it is probable that it will not pay to use cast iron; but whatever may be the economic aspect of the question it is interesting to note that more than one firm has made machines with cast-iron magnets. We have recently described a machine of this description built by Messrs. PARIS AND SCOTT. Messrs. PATERSON AND COOPER have also brought out a single horseshoe machine, in which the pole-pieces, magnet limbs, and a portion of the yoke are in one casting. The remainder of the yoke and the bed-plate form another casting. In this machine the armature is above, and its spindle is supported in two bearing standards bolted to the bed-plate. The magnets have not been cast with the bed-plate because of convenience in handling, but even with the horizontal joint dividing that portion of the yoke which is cast with the magnets from that which forms part of the bed-plate, the amount of tooling required in this machine is reduced to a minimum. The joint is naturally of large area, and being traversed by only a portion of the lines offers, therefore, less magnetic resistance to the total flow than the usual construction, where each magnet limb is separately bolted to the yoke. Cast-iron field-magnets are also employed in Mr. PARSONS' turbo-electric generator, though in this case the material was chosen not so much for economic reasons, as because with the high speed of the armature, strength of field is not so much a necessity as in the ordinary type of dynamo. As we have recently described and illustrated this machine we need not dwell upon it at the present time, beyond recording the fact that a fine battery of these generators was at work with perfect success during the Newcastle Exhibition, lighting nearly the whole of the buildings by means of Parsons' large glow lamps. Owing to their compact arrangement and small weight, these generators find much favour with marine engineers for ship lighting.

As regards the armatures of continuous current dynamos, the present tendency is towards a more universal adoption of the drum type. So long as the Hefner-Alteneck patent was in force, not many makers did care to adopt a type of armature on which they would have had to pay royalty, but with the expiration of this patent the use of the drum-winding was thrown open to the public, and some of our leading makers have during the year built dynamos having such armatures. Messrs. ELWELL-PARKER showed a vertical single horseshoe dynamo, with drum armature, at the Newcastle Exhibition; and Messrs. GOOLDEN have adopted long drum armatures for some of their direct-driven dynamos. Messrs. PARIS and SCOTT have also brought out some two and four-pole machines, having a modified drum armature. A good deal has been said and written regarding the relative advantages of cylinder and drum armatures, but most investigators have limited themselves to what may be called the more elementary considerations of length of wire per volt, resistance and facility of manufacture and repair. There are, however, some other points involved, which, although of some importance, seem to have hitherto escaped general notice, and as the present tendency is towards the adoption of drum armatures in preference of the cylinder type, a few words on the subject may be of interest. In the first place, it is well to notice that with the exception of EDISON and WESTON, dynamo makers generally have not adopted the type of armature originally introduced by Messrs. SIEMENS, as long as that firm could demand a royalty for use of the drum-winding. This winding was only taken up by some of the leading makers after the time for demanding royalties had elapsed. It would therefore appear that the possible advantages of drum-winding were not sufficiently great to induce firms to adopt the method as long as there was anything to pay for it. But even a small advantage, if it can be obtained without sacrifice in another direction, is worth having, and that the drum is in some respects better than the cylinder is pretty generally acknowledged. The greatest objection to drum-winding has hitherto been the difficulty of repair. If a coil burns up in a cylinder armature it can be replaced without disturbing the rest of the winding, but in a drum the whole of the winding must generally be removed before the repair can be effected. As time goes on this objection, however, loses much of its original force. The workmanship and materials now used in dynamo construction have been so far improved that a short circuit in a single coil is now a very unlikely thing. We do not say that a breakdown will never occur with modern machines, but it is more likely to be of a mechanical character than a local failure of insulation; or if it be an electrical breakdown it is more likely to be due to rough usage, affecting more or less the whole machine. In such failures the greater accessibility of any single armature coil is of comparatively little importance. But granting that the cylinder has still some advantage over the drum in this respect, the latter has the advantage of a larger mass of iron and a smaller self-induction, besides requiring less wire. Owing to nearly the whole of the interior of a drum armature being available for the flow of lines, the density of lines need not be so great as in a cylinder core, thus reducing the liability to heat, and economising power, whilst the smaller self-induction and reduced length of wire permits larger currents to be given off without sparking at the brushes or excessive heating of the conductor. Thus weight for weight a drum machine will have more output than a cylinder machine. This advantage, in our days of keen competition, cannot fail to attract the serious attention of dynamo makers, and we may therefore expect that during the year upon which we are now entering dynamos with drum armatures will come largely into favour.

It is curious to note that whilst other makers have thus taken the drum armature, Messrs. SIEMENS AND HALSKE, of Berlin, who originally introduced it, have begun to abandon it in favour of the Gramme ring. During the year a type of dynamo has been developed in Germany which necessitates the employment of the Gramme armature, whilst, at the same time, reducing the total weight of machine to even a larger extent than can be accomplished by the substitution of the drum for the cylinder in the usual two-pole machines. We refer to multipolar cylinder machines with internal magnets. Priority of the invention, if such it can be called, is claimed by four German firms, viz., Mr. FEIN, Messrs. SIEMENS AND HALSKE, Messrs. GANZ AND CO., and the HELIOS COMPANY. Briefly described, the machine consists of a fixed star-shaped system of electro-magnets, round which revolves a Gramme ring. The core of the armature consists of iron plates held together near their outer periphery by insulated bolts inserted parallel to the

Digitized by Google

axis and prolonged to one side, where they are attached to a supporting ring, which, by means of arms and a central hub, is mounted on the spindle. The centre or yoke of the star magnet is bored out to let the spindle pass. The great advantage of this design is, that for a given sectional area of magnet cores and a given space available for the exciting coils, the weight of the field-magnets is reduced to a minimum, whilst the total length of magnetic circuit is also much shorter than in the usual design of dynamos with external magnets. There are, however, some practical disadvantages. The armature being overhung is more difficult to balance; it is more liable to injuries, and the active wire—which in this case is on the inside of the ring—cannot be so simply and securely fastened as in the usual type of armature. On the other hand, the output of internal-magnet machines is very great, as compared with their weight and speed. Thus, for instance, a 15-kilowatt machine, made by Mr. FEIN, weighs only 14½cwt., or 108lb. per 1,000 watts output. The speed in this case is 520 revolutions. Messrs. SIEMENS AND HALSKE have built during the year a fair number of internal-magnet machines, amongst which were four for 75 kilowatts output each, for the lighting of the Frankfort Railway Station. These are probably the slowest speed machines ever constructed; they are direct driven, each by its own vertical twin engine, at only 150 revolutions per minute.

The year 1887 has also seen a new application of dynamo machines for the conversion of high-tension continuous currents into low-tension continuous currents, or, to speak more correctly, the revival of an idea originally conceived by Gramme in 1874, and published by Niaudet a year later. The apparatus constructed by Gramme was a magneto machine, the armature of which was wound with two circuits, in the same way as that of the modern rotary transformer; but the primary object of the inventor was not the translation from a high to a low tension, but the reverse. He used Bunsen cells as a source of electricity, and by means of his apparatus obtained a higher electromotive force and a smaller current than corresponded to the battery, so that a few large cells could do the work of a great number of small ones. A reduction of the number of cells necessary to work over a telegraph line of high resistance seems to have been the principal aim for which Gramme devised his apparatus, and to all appearances he never foresaw the possible application of a rotary transformer for transmitting and distributing electrical energy over long distances. This application has been perceived by Edison, who during the last few years has taken out several patents for induction apparatus, whereby continuous high-tension currents can be translated into those of lower tension. In some of these designs the induction coils are stationary, and the commutating device only is in motion, worked by an electro motor, whilst in others the induction coils (arranged in the form of an armature) themselves are in motion. The latter arrangement, which in principle is identical with Gramme's original design, was taken up in England in the beginning of the year by Messrs. PARIS AND SCOTT, who actually showed a transformer at work at the close of the Newcastle Exhibition. As we have fully described this machine and the excellent results obtained with it in our issue of 28th October, 1887, we need not say more about it at present. In Germany, the question of continuous current transformers has been taken up by Messrs. JEHL AND RUPP, who have devised several types, some with stationary coils and a special distributing commutator, and others with compound wound armatures revolving in stationary fields. The fact that only one firm amongst the many English firms who build dynamos has taken an active interest in the matter of continuous current transformers seems to show that either there is no great prospect that there will be a want for such appliances in the near future, or that the practical difficulties in the construction and use of these transformers are greater than at first sight appears.

In the application of continuous currents for motive-power purposes, the year 1887 has left a fairly satisfactory record. Quite a number of electric railways and tramways were opened for traffic in America, and some of these of considerable extent. Electric locomotives of large size have been built by our trans-Atlantic cousins. As examples, we might cite the BENTLEY-KNIGHT locomotive and the FIELD locomotive. Details regarding the performance of the former have not yet reached us; but as regards the latter, trials recently made on the New York elevated railroad were exceedingly satisfactory. The locomotive weighs thirteen tons, of which nine tons go to the motor and four tons to the body of the vehicle and the regulating apparatus. In this engine the armature spindle is connected by side rods and cranks directly with the driving wheels, and develops an average of 40 to 50 horse-power. Recently storage batteries have also been introduced for working electric tramcars in America, and there is every indication that the present year will see a large extension of this system. On the Continent, which some years ago took the lead in matters connected with electric traction, little has been done during the past year, but in England good progress has been made. Of existing railways, those at Brighton and Portrush, the Bessbrook-Newry line, and the Ryde tramway have continued to work without a hitch. The difficulty experienced with the underground conductor on the Blackpool line has been successfully overcome by the employment of better insulators, and this line has now for some time again been in perfect working order. Of new enterprises in electric traction should be mentioned the Stratford and Manor Park tramway, where horses and Elieson's electric locomotives are used to draw alternate cars, and the Shoreham tramway, on which, during the summer, the cars of the Electric Traction Syndicate were run for experimental purposes. The Elieson locomotives have done plenty of hard work, and the fact that they could run in between the horse cars without disorganising the service shows that they are perfectly reliable. Neverthless, we look upon the Elieson system as essentially a pioneer system. Until tramway companies can be convinced that electric traction is not only as cheap or cheaper than horse traction, but also equally reliable, we cannot expect them to alter their rolling stock and to fit their cars with motors and batteries. They might, however, agree to attach their ordinary cars to electric locomotives, because this would always leave them free to revert to horse traction should the experiment prove a failure, and it is for this reason that we look upon Mr. ELIESON's locomotives as a pioneer system. But let it once be proved to the satisfaction of tramway directors that electric traction is cheap and reliable, then the separate locomotive must make room for the self-contained car, such as is used by JULIEN in Brussels, HUBER in Hamburg and Cologne, RECKENZAUN in Philadelphia, and the ELECTRIC TRACTION SYNDICATE in Shoreham. The application of motors for other than traction purposes has also made satisfactory progress during the year. The most perfect example of electric transmission of energy yet existing is probably the installation which the OERLIKON WORKS put up between Kriegstetten and Solothurn, Switzerland, in the beginning of the year. Recent trials have shown that the commercial efficiency of the whole plant averages 75 per cent., a result which, considering that the distance of transmission is five miles, surpasses anything yet accomplished in transmission of power. Coming nearer home, it is satisfactory to note that Messrs. IMMISCH AND CO., who have made a speciality of electro motors, have during the year

Digitized by Google

been fairly busy with transmission-of-power plants, both for the home and colonial markets. Electric transmission of energy, although only over short distances, is also employed in Mr. F. J. ROWAN'S ingenious machine tools, which were exhibited at Newcastle. These tools are specially intended for use in ship yards, and are provided with powerful electro-magnets, by which they are firmly attached to the ship's side.

Our brief review of the year's progress in this branch of electrical industry would be incomplete were we to leave out all mention of the progress made in alternate-current machinery. In America, where the WESTINGHOUSE COMPANY have acquired the Gaulard-Gibbs patents, distribution by alternating currents is fast coming to the front. The company use a dynamo designed by their own electrician. It has a drum armature, containing an iron core, and is provided with Pacinotti teeth. The field consists of a circular yoke and magnet cores radiating inwards, and in this respect is similar to the alternate current machine made by Messrs. ELWELL-PARKER for the Eastbourne Central Station. But the armature is entirely different. By adopting Pacinotti teeth and saddle-shaped coils, each surrounding one of the teeth, the magnetic resistance of the Westinghouse machine is considerably reduced, whilst at the same time nearly the whole of the wire on the armature is active, there being no useless wire, such as the internal wire in a Gramme ring or the end connections in an ordinary drum armature. The machine should therefore have a large output for its weight, and in so far the design seems good. There is, however, the practical difficulty that the Pacinotti teeth are themselves liable to heating, and to cause heating of the pole-pieces. This defect in continuous-current machines has been almost entirely overcome by making the teeth very narrow, but for obvious reasons the same remedy cannot be applied in an alternate-current machine, and until some other remedy against heating by eddy currents is discovered we think that Pacinotti armatures will not prove satisfactory in such machines. The prevailing opinion, in England at any rate, is in favour of either a smooth core or an armature without any iron at all. In the two types of machines at present most widely used in England—viz., the Siemens and the Ferranti machine, the armature contains no iron, whilst a smooth core of coiled iron wire is employed in Messrs. ELWELL-PARKER'S machines. A large machine of this type has recently been delivered by this firm to the Brighton Central Electric Light Station, but as it has not yet been regularly set to work, we cannot say anything about its performance. The type is the same as that of the Eastbourne machine above mentioned, but the armature is of much larger diameter and proportionately very short. In order to avoid binding hoops the outside of the core has a considerable camber, so that the wire can be firmly wound on, and will not be lifted by centrifugal force. Alternate-current machines have during the year received attention from various quarters. The brothers HOPKINSON have got out a new type of dynamo for alternating currents, and a large machine of theirs is now completed; Mr. MORDEY has also been engaged for some time with a machine in which the field-magnets revolve and the armature is stationary, an excellent plan for insuring high insulation; and Mr. KAPP has brought out a new machine in which the armature is of the disc pattern, the core being composed partly of iron tape and partly of iron wire. The copper winding is secured by phosphor bronze castings inserted between adjacent armature coils. The field-magnet system is similar to that of ordinary multipolar disc dynamos. The advantage of disc armatures for alternate current machines is, that whilst the core can be smooth to prevent heating of pole-pieces, nearly the whole of the wire is actually under the influence of the field. This secures a large output for small weight, and the first machine made by Mr. KAPP, and which we saw tried in the early part of last autumn, gave an output of one kilowatt for every 100lb. dead weight. Another, but much larger machine, is now in course of construction. It is intended for an output of 40 kilowatts, and has cast-iron field-magnets, this material having been chosen to reduce the labour which would otherwise be required in fitting a large number of wrought-iron magnet cores into cast-iron yokes.

In transformers for alternating currents the year 1887 has brought several novelties. Leaving aside the transformers of the Ferranti and Hall type, which properly belong to the previous years, there were brought out last year the following transformers, amongst others:—One by WESTINGHOUSE, in which the primary and secondary are wound upon each other, and the core is afterwards inserted in the shape of rectangular frames of thin sheet iron, having a central webb. The webb is connected with the frame on one side only, so that it can be bent up, allowing the frame to be slipped over the coils, and when in position the webb is bent back again into the plane of the frame. These transformers are placed in watertight iron boxes and are generally fixed out of doors on the poles which carry the primary and secondary circuits. Another transformer has been devised by Mr. MORDEY. The outer portion of the core consists, as in the Westinghouse transformer, of a rectangular frame, and the portion stamped out from the middle is laid across to form the central webb, so utilising all the metal. In this case the length of the outer edges of the rectangle must obviously be in the proportion of 2 to 3. Mr. KAPP has brought out a transformer, the core of which consists of U-shaped stampings laid together to form a double trough. The coils are separately wound, and after being placed into the troughs the latter are closed by covers made from the metal which was stamped out of the U-pieces. Messrs. GAULARD AND GIBBS also use U-stampings, but place them in a circle, thus forming a kind of Zipernowsky transformer; but with this difference, that instead of employing a core of iron wire wound over the coils in an irregular manner, and thereby rendering access impossible, the core is neatly arranged and removable for examination and repair of the coils.

Taking it altogether, the record of heavy electrical engineering during the past year is fairly satisfactory. If central station lighting has not progressed with us at the same rate as is the case in America and on the Continent, some good work has been done in other directions; and with all their improved machines and appliances electrical engineers can now feel confident that, if the call for "more light" from central stations comes—as come it surely must—they will be in a position to supply the wants of the public without risk of failure.

Electric Lighting of Trains in Canada.—Electric lighting of trains is receiving attention in Canada. The first train in the Dominion to be so lighted is regularly running between Montreal and Ottawa. A Pullman drawing room car, one first-class and one second-class, are fitted with incandescent lamps and Julien storage batteries. There are nineteen lamps in each of the two former cars, and thirteen in the latter. When arrangements are completed, trains will run from Halifax and St. John to Quebec and Montreal, lighted by electricity and heated by steam. It is reported that the Canadian Government has appropriated for electric lighting and steam heating on the Inter-Colonial the sum of $24,500, and that road is actively at work equipping two trains with Julien storage batteries.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

(*Continued from page 180.*)

CHAPTER VI.—*Current Indicators.*

54. The laws of the current, and the relation between E.M.F., resistance and current having been considered, we shall now examine some of the instruments used to indicate the presence of a current, these being termed *detectors* or *indicators* in distinction from galvanometers or current measurers. It will also be shown how detectors may be calibrated so that their indications may be made to show the exact strengths of current passing through them.

55. Detectors are in constant use on land-line telegraph circuits, one being fitted to each Morse instrument, so that when the operator is sending a message he may observe that his current is going out to line all right. And when the distant station calls up the call is shown on the detector as well as the Morse armature, so that if the latter should fail for any reason there will still be always a visual indication attracting the attention of the operator.

Detectors are very useful in tracing a fault on an instrument or line or in identifying certain wires from a large number. The manner of doing these will be explained as soon as the instrument itself has been considered.

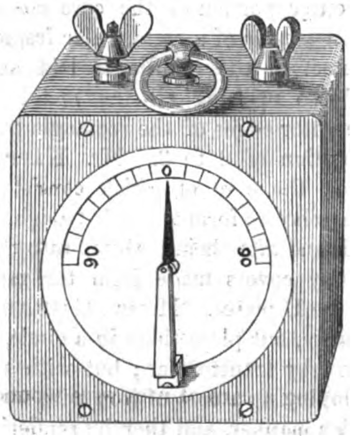

FIG. 18.

56. One of the most useful and common forms is shown in Fig. 18, which will indicate the *direction* of a current by the needle being deflected one side or the other. It is advisable to ascertain which way the needle moves with a given direction of current through it, as we shall require to know this frequently when testing with the instrument. Suppose that on connecting it to a voltaic cell, as in Fig. 19, the needle moved to

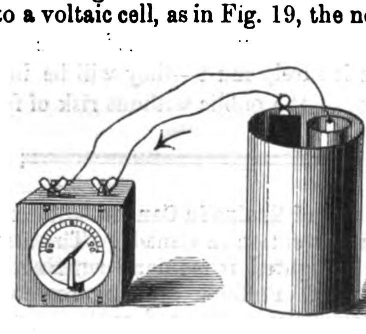

FIG. 19.

the right, then knowing that the current leaves the carbon plate in the cell and enters the detector by its right hand terminal, as shown by the arrow, we should know that the needle would always deflect towards the terminal where the current entered or towards the positive terminal. For if we reversed the wires on the detector, so that the current entered by the left-hand terminal, the needle also would be deflected to the left.

57. All instruments do not deflect the same way for the same direction of current through them. The direction in which the needle of an instrument will deflect when a given current is supplied to it depends on three things:—

1. The position of the poles of the needle relatively to the coil when the former is at rest.
2. The direction of winding of the instrument coils.
3. The connecting up of these coils to the instrument terminals.

As an illustration, we might cause the deflection of the above detector in Fig. 19 to be always towards the *negative* terminal by altering *either* of the three conditions mentioned. But if we altered the instrument by any two of these conditions, say the position of the needle at rest, and the connecting up of the coils to the terminals, we should not alter the direction of deflection for a given current, since these two changes would neutralise each other. Similarly, if we altered all three conditions, we should *reverse* the deflection.

58. There are two needles to the instrument, one, the smaller, N S, being of hard steel well magnetised and

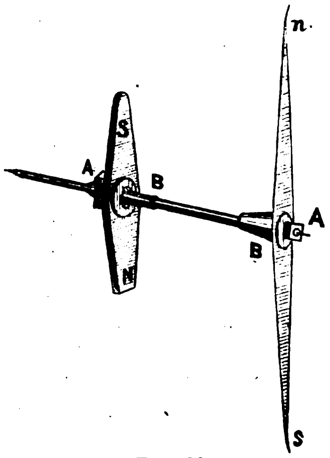

FIG. 20.

weighted at the end N, this end being made broader. The use of this is to bring the needles back to zero again after being deflected, or, in other words, to act as a controlling force (viz., that of gravity on the larger end) to the system. Fig. 20 shows the needles and spindle detached from the instrument. The longer needle *n s* which is seen outside in Fig. 18 has its poles reversed to those of the inner

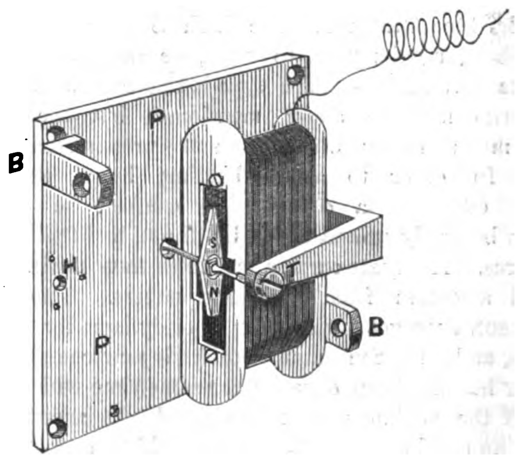

FIG. 21.

needle N S. The reason of this will be explained with the action of the coil.

Both needles should be perfectly parallel, to ensure which each is pierced with a square hole at its centre, which fits over a square key on the brass hubs B B; and the latter having a very fine thread cut permits of tightening up the needles securely in position by a little square-headed nut

(shown at A A), which can be screwed on by means of a small pair of pliers.

Turning now to the interior of the instrument the two coils are wound on brass bobbins, one of which is shown mounted in position in Fig. 21, the other having been removed to expose the needle, N S, to view. The mounting of the spindle can also be seen, and the freedom of the latter to turn can be adjusted to great delicacy by the screw, T. The interior space of the coils in which the needle moves is very little larger than the needle itself; which brings as much turning force as possible to bear on the needle when the current is on; this makes it important to fix the coils accurately in position, so that the needle may not touch the sides during any part of its play. The brass bobbins are therefore screwed on to the brass plate P with little brass pins to act as guides and keep them in position. The screw hole of the removed coil is seen at H and the three guide holes round it. The brass angle pieces B B serve to screw the plate and coils when adjusted inside the wooden box of the instrument.

Regarding the winding of the coils, it should be remembered that the current must flow through both coils in the same direction, since the two coils should form virtually one electro-magnet; in fact, the reason for the electro-magnet being made in two coils is only for facility of construction and getting at the needle conveniently. In order to be able to detach each coil separately from the instrument (for convenience of adjustment) the coils are not connected by a wire between them, but the underneath end of each coil is soldered on to the brass bobbin. So that before starting to wind a coil the end of the wire is soldered to the brass bobbin, and when the coils are finished and screwed into their places electrical contact is made between the two *inside* ends of the coils through the brass work.

(To be continued.)

THE USE OF ACCUMULATORS FOR TELEGRAPHY BY THE EXCHANGE TELEGRAPH COMPANY.

BY MR. F. HIGGINS.

During the past six months the Stock Exchange tapes have been worked from the Cornhill office by means of accumulators, which have replaced 2,000 of the batteries formerly in use. These accumulators are grouped in three sets of seventy in series, and are of the 7 L size, contained in glass cells.

As a result of our experiments to ascertain the best conditions for the employment of accumulators in this work the following arrangements have been adopted :—

The plates are placed double the usual distance apart, in order to reduce polarisation, internal leakage, and contacts due to particles of scale, &c. The glass cells have an extra depth, making them 5in. above the tops of the plates, to admit of the employment of spray interceptors of glass, on the principle pointed out in a communication to the Society of Telegraph-Engineers and Electricians in March, 1886, to preserve the insulation, and restrain the acid from entering the air and corroding the connections and surrounding machinery.

An important economy of motive power is obtained by increasing the distance apart of the plates. Those which are only ⅛th of an inch apart take 10 minutes longer per day to charge up to the gas-producing point, with the current at 15 amperes, than do similar 7 L size plates at ¼in. apart, and the motive power thus saved amounts to 14 horse-power-hours per week. The state of affairs inside can also be readily examined; should scaling take place the flakes can get to the bottom of the cell without hindrance, and the reduction of polarisation, due to the increased volume of acid between the plates, contributes materially to the steadiness of the current.

The following observations of the charging and discharging current were made, a portion of the discharge, which is intermittent, being caused to pass through a copper voltameter for this purpose :—

The potential of the dynamo was 194·15 volts, that of seventy accumulators while enveloped in nascent gas as nearly as possible at their highest 154·46 volts, the resistance of the external circuit of seventy cells being 1·236 ohms, and that of the dynamo armature 1·254. The available potential with this resistance should cause a flow of 15·9 amperes; but the observed current was between 15 and 16 amperes. The slight difference may be due to the less perfect contact of the brushes when in motion, and also to the slight increase of temperature in the armature. The charging current was equal to about 25·35 horse-power-hours, and the discharge as measured by the decomposition effected was equal to 88·128 ampere-hours at a potential of 154·46 volts, or about 18·24 E.H.P.

The useful return appears, therefore, to be about 72 per cent.; but if the difference of potential between the charging and discharging current be deducted, the loss in the battery itself appears to be only 7·7 per cent., some part of the latter being purposely wasted in overcharging.

A peculiar phenomenon was noticed in connection with these batteries which caused the repeated failure of the india rubber bands, and was a source of inconvenience at the commencement of their use; but a study of the effects and the discovery of the cause enabled us to provide a remedy which is perfectly effectual in protecting bands which would otherwise not stand for 48 hours.

It was found that when imperfectly cured india rubber is placed near to or in contact with the negative element of an accumulator, oxidation, and consequent loss of elasticity, takes place opposite the positive plate. The same oxidation occurs under similar circumstances with some other inflammable hydrocarbons, but not with well vulcanised india rubber, which is not so combustible or readily oxidised as pure or slightly vulcanised india rubber. Insulation by means of glass plates on *every* side is a perfect protection to the bands, not one of which has failed since having been so provided.

No sign whatever of buckling or flaking has yet appeared, and we do not anticipate working under the conditions which are necessary for their production. A most successful method to produce buckling experimentally is to associate cells of different capacities or different charges in series, and exhaust, or nearly exhaust, the larger. This, if repeated a few times, will not only cause the plates to buckle, but to shed their plugs in showers.

It is sometimes impossible to avoid the occurrence of these unfavourable circumstances in the case of cells which are leaking internally, but if the plates be placed further apart than usual, and the cells kept dry outside by spray arresters, and regularly charged, they may perhaps be reduced to a minimum. Slight buckling can also be produced by discharging too rapidly, but no damage, as far as my experiments have gone, results from repeatedly charging and completely discharging cells.

The crippling of plates by their own weight may be avoided by suspending them from above; as at present arranged a great responsibility rests upon the tenderest part.

The current obtained from these batteries for working our type-printing apparatus is steadier than from the primary batteries previously employed, and shows no perceptible variation from day to day. But they are not suitable on account of their size for small offices, which would require less than 1,000 cells of primary batteries, because accumulators to furnish the maximum working potential of 300 volts would occupy a space greater than would be required for the primary batteries, and entail about the same attention in charging.

The greatest volume of current employed at one time for this service is 35 amperes, and the time necessary for charging may be calculated from the number of words transmitted to within a few minutes daily.

Electric Burglar Alarms.—The *Western Electrician* mentions that "the New York police calculate that if burglar alarms were not in such general use in that city it would be necessary to employ fully twice as many patrol men to prevent burglaries. They declare that these automatic alarms are of the greatest use in preventing crime or making it ineffective.

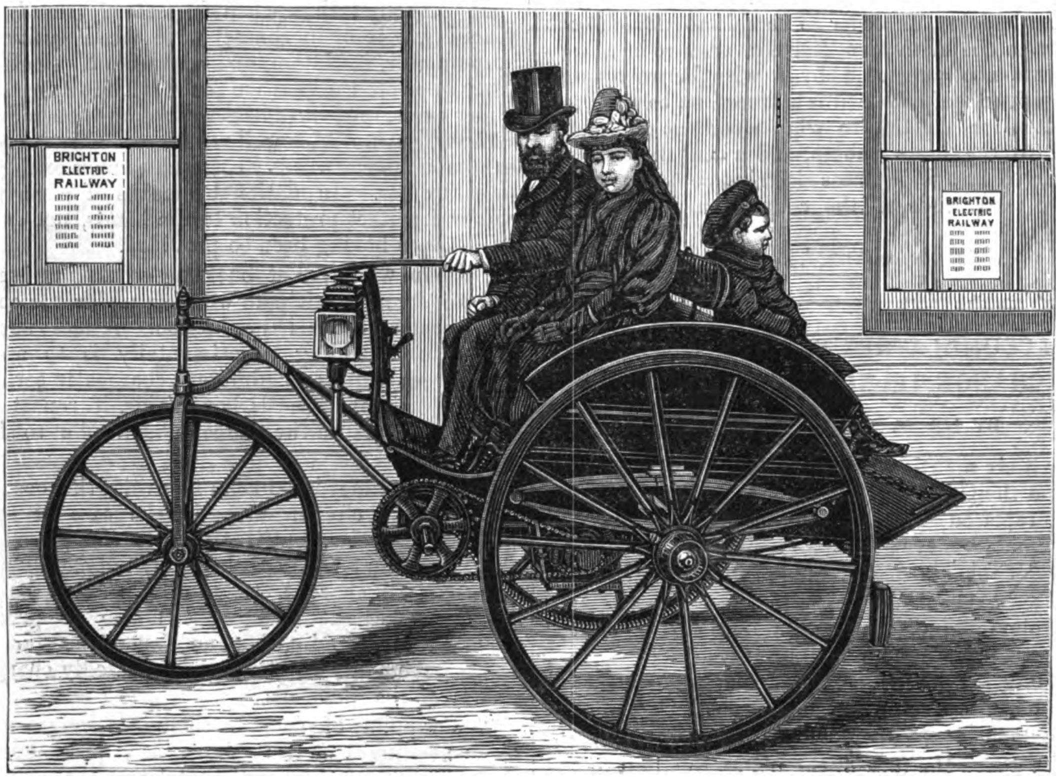
VOLK'S ELECTRIC DOG-CART FOR ORDINARY ROADS.

Mr. Magnus Volk, of the Brighton Electric Railway, has recently turned his attention to the application of electric traction to vehicles running upon ordinary roads. The dog-cart represented in the adjoining engraving was built by Messrs. Pack, coach-builders, of Brighton, and is driven by an Immisch motor of ½ horse-power type. The current is supplied by 16 E.P.S. accumulators, which at the normal rate of discharge are good for a six hours' run. The cells are placed under the seats. The motor is supported by hangers under the body of the car, and drives on to a counter-shaft in front by a Renold's steel link chain. Upon the inner side of the rim of the right-hand wheel, which is 4ft. in diameter, are a number of blocks fixed about 1ft. apart, and a second steel chain passes from the counter-shaft around these blocks. The arrangement is neat in appearance, and has the advantage of reducing the weight of the gear to a minimum.

The motor at present employed weighs 40lb., though it is scarcely large enough for the work it has to do. The experiments so far made have resulted in obtaining valuable data as to the tractive force required for vehicles on roads of various kinds. On asphalte the tractive force is less than on a grooved rail, and a speed of nine miles an hour can be obtained, whereas on a soft macadam road only four miles an hour is possible. With a load of two persons a grade of 1 in 30 can be surmounted.

The vehicle is the object of much attention just now in Brighton, and taken altogether as a first experiment the results may be considered to be interesting and satisfactory.



VOLK'S ELECTRIC DOG CART.

ELECTRIC LIGHTING EXPERIENCES IN INDIA.

BY L. A. DAVIES.

Some of the readers of *The Electrician* may have heard of he big steel girder bridge erected by the Oudh and Rohilkund Railway Company over the Ganges, at Benares, and opened last month by the Viceroy, and now known as the "Dufferin Bridge."

Nearly all the rivers of India are subject to heavy spates during the monsoon, which put a complete stop to all work in the river-bed for some four or five months in the year, and thus render it necessary to take advantage of every hour of low water. The Oudh and Rohilkund Railway Company accordingly purchased a plant of electric lamps and dynamo, to enable them to carry on the construction of their great bridge by night, and I was sent out to fix and work the lights.

The piers were being built and sunk when I reached Benares. These are of brickwork, and of great size. Everybody concerned was positive that it would be quite impossible to do brickwork of the high standard usual in Indian railway works by any artificial light, and as to working the 20-ton cranes and big diggers, it would be folly. The drivers, coolies, &c., would tumble off the staging, and all sorts of accidents would happen. However, as the lamps were there, and had been paid for, I was allowed to hang them up, with the result that work went on as merrily by night as by day, to the great astonishment of the natives and the satisfaction of all.

We had a rather neat way of hanging the lamps for pier-building. There was nothing extraneous whereon to hang them, the piers being simply *growing* red brick islands in the river bed, so I got made some bamboo tripods sufficiently high, and hung the lamps from a shackle on the iron bolt connecting the three legs. When the bricklayers worked up to the tripods my coolie in charge shifted them on to the new course, and so bricklayers, coolie, tripods, and all rose in the air together.

When the time came for erecting the girders the old fears were expressed that it would not be safe to lift such heavy weights by artificial light, and the English riveting foreman vowed they would not be able to see whether their rivets were properly heated or not; however, as before, a trial showed the unreality of the difficulties raised, and erecting and riveting proceeded, like the building and sinking, night and day. The resident engineer, Mr. Granville Walton, was quite alive to the need of making the most of the low-water season, and used the light wherever possible, with the result that every operation went on by its means. Lamps were hung from the corners and centres of the lofty gantries which carried the hydraulic riveters, and from the Goliath cranes, all being connected to the mains by loose insulated wires, thus in no way interfering with the necessary movements.

The plant used was of the Gülcher type, which necessitated the use of a parallel system of connection. The wiring was

Digitized by Google

thus rather complicated, especially as none of the lamps were often in the same place for two nights together. Short circuits were of pretty frequent occurrence, nothing but bare wire having been sent out originally; but a simple system of methodical disconnection soon made the men expert at localising the fault even at night, and I made a practice of testing for insulation each main, with all lamp switches open before starting. I set off against all this the freedom of anxiety as to nasty shocks obtained by using a low E.M.F., and the sufficiency of slight insulation. Whilst employed at Benares I went up to the other end of the Oudh and Rohilkund Railway Company's line to put down an installation of two Brush dynamos and twenty-six lamps to be used in the construction of another bridge over the Ganges at Balawali, nearer its source, and I was always very much afraid that some careless native would hurt himself in spite of the well-insulated cable used. The simplicity of construction peculiar to the Gülcher lamp renders it very suitable for use with native assistants, as they soon learn to clean and recarbon it, and even to adjust it. The Gülcher dynamo sent to Benares was of a rather ancient pattern, and though electrically very efficient, was not so satisfactory from a mechanical point of view. It was awkward to open up, and still more awkward to put together. The wires connecting the armature and commutator ran through a hollow bearing, coming out in a bunch before spreading to the commutator, and this bunch was a sort of half way meeting place for lubricant from the bearing and copper dust from the commutator. There were also two unncessary brushes. I got a pedestal cast, and a new spindle turned, so as to get a bearing outside the commutator, and connected up the armature sections so as to do away with the two extra brushes. However, I find that all these improvements, and others equally important, have been effected in the machines as now made by the Gülcher Company.

Four Siemens differential lamps, with water-tight cases, and two small Siemens dynamos had also been supplied to the bridge works for diving purposes. We tried to make use of these when divers were at work cutting into the clay bed in the pier wells; but the muddy state of the water rendered them quite useless. I stripped and took a plunge into one of the wells myself to see what amount of light one of these lamps was giving under water, and found that a yard from the lens the arc looked about as bright as a lighted cigar end on a foggy night.

The whole installation, however, was such a success that five more lamps were ordered to make up the full complement of the machine, and also fifty incandescent lamps of the Swan-Edison type, and I myself was kept in the service of the company for four years, instead of the six months for which I was originally engaged.

I would advise any brother electrician going out to a distant country to thoroughly inspect the apparatus he is going to use before starting. I, unfortunately, had not the opportunity of doing this, everything having been sent off round the Cape in a sailing vessel before I was engaged, the consequence being that I was put to innumerable shifts and dodges to supply deficiencies. Nothing at all had been sent in the way of resistances for the lamp circuits. Not an instrument of any description, not even a speed counter. Of course, when I arrived there and discovered this, I indented for everything needful, but in the meantime had to rub along by hook and crook. I will just mention here that dynamos and lamps should be fitted with vulcanised fibre insulating washers and brushes when intended for India, as ebonite seems to crack and perish in so hot a climate.

Hindoos and Indian Musselmans are very good sort of people to work with. They are fairly quick and tractable, and soon pick up as much as is necessary for them to know. At first, of course, I had to do everything myself both day and night, but by degrees I got a good crowd of men together—some, of course, better than others—and was enabled to take matters more easily. The native idea of electricity was very amusing. I have often seen an intelligent Babu take up gingerly the end of a wire to look for the hole through which the "howa" travelled. "Howa" means air, but is also the name given to steam, and they (the natives) firmly believed that the steam in the boiler passed along the wires and caused the lamps to burn after having been rendered invisible in the "masine." "Howa" it began and remained, according to them. Some few, however, called it "bijli," or lightning. A good deal of valuable awe attached to me as the sahib who controlled and had in subjection this mysterious force and its appliances, and a dimmer halo surrounded the heads of my men in the eyes of their countrymen. Coming into the machine room at night I would often find the little Mahommedan lad, Ghazi, who had charge of the dynamo bearings and brushes, the centre of a crowd of wealthy Mahajans and Babus from the city, who would be humbly questioning him as to the wonderful properties of the machine, and he arrogantly giving some fearful theory of his own as gospel and pocketing annas for magnetising their knives on the magnet poles.

KENNEDY'S SINGLE-MAGNET DYNAMO.

We illustrate herewith two types of machine, recently introduced by Mr. Rankin Kennedy, of the Woodside Electric Works, Glasgow, in each of which the field is wound with a single coil. In the machine shown in Fig. 1 the field-magnet

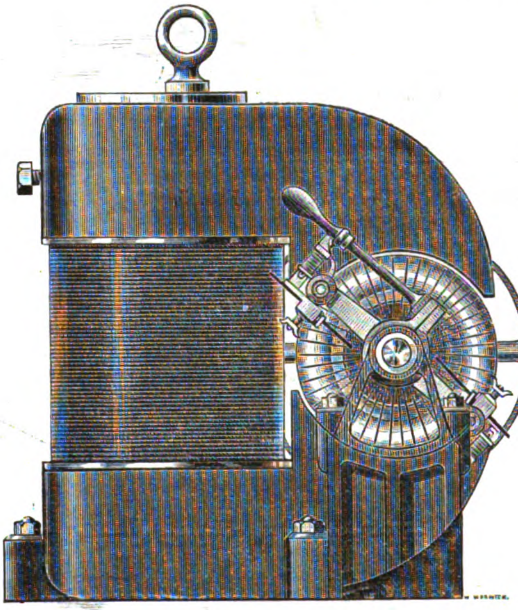


FIG. 1.

is made of three pieces, with only one field bobbin. The core of the bobbin is made of hammered scrap iron, and measures 10in. in diameter and 14in. in length; the pole-pieces are of soft cast iron, and are of much greater cross section than the core of the bobbin. This construction has the advantage of simplicity, combined with compactness and low magnetic resistance. The armature is built of charcoal iron discs, and the core is turned true, outside and inside, and mounted on metal spokes on a steel shaft; the outsides of the armature are usually turned up true on the shaft. The armature core of this machine is 12in. long, 10in. in diameter outside, and 6in. inside diameter, the depth of core being thus 2in.; the armature is wound with flat wire 5mm. by 3·5mm., one layer outside. The current allowed for this armature running constantly for long runs is 90 amperes. The commutator is made of solid-drawn copper sections, insulated with mica, and is of large size. The brushes are adjustable in all directions, and the pressure on the commutator is adjusted by springs. The brushes require a slight adjustment for varying loads, but at a speed of about 900 revolutions this machine gives 102 volts at the terminals.

On next page is a copy of a report furnished by Prof. Jamieson of a ten-unit dynamo of this type.

Report on Rankin Kennedy's Single Horseshoe Magnet Dynamo.

I tested this dynamo on Friday, the 4th November, 1887, and had it run continuously for eight hours at full load (with the exception of about half an hour during the workmen's meal hour).

The dynamo, which is a self-regulating, compound-wound machine, consists of a single horseshoe magnet, with an armature of the Gramme type. The core of the magnet is made of soft hammered scrap iron, the pole-piece of hematite cast iron, and the armature core of soft charcoal iron washers.

The whole machine is exceedingly simple, strong, well-proportioned, and well put together. It is just the kind of dynamo for factories, mills, workshops, and steamers, for it may be left in charge of any ordinary mechanic or fireman, with a minimum chance of its getting out of order.

All the adjustable parts are readily accessible, and the armature may be removed and replaced in as short a time and with less trouble than almost any form of dynamo that I have seen. There is no perceptible sparking at the brushes. The commutator and the brushes, both from their construction and composition, as well as the freedom with which the latter can be adjusted, are calculated to last for a very long time. None of the parts of the dynamo showed any signs of undue heating, and the ventilation of the armature was all that could be desired.

From a sample of my electrical tests it will be observed that the dynamo gave an "output" of 10,850 watts or 108·5 amperes, and 100 volts at 620 revolutions per minute, and that the electrical efficiency was 89·3 per cent.; which is good for a dynamo expressly designed as a cheap, practical, workshop or factory machine, and not as a special test dynamo for experimental purposes.

With due attention to the oiling of the bearings, &c., there is no reason why this machine should not work continuously for a week or more on end, without giving the least trouble; and if the future machines made by the same firm are as carefully designed and constructed as the one I had the pleasure of testing, they should give satisfaction to the purchaser. It is a distinct improvement on their former dynamos. (Signed)

Andrew Jamieson, M.Inst.C.E.

Sample of Electrical Tests.

Resistance of armature, warm,	= ·04 ohm.
Resistance of magnet shunt, warm,	= 20 ohms.
Resistance of magnet main coil, warm,	= ·03ohm.
Current in working circuit	= 108·5 amperes.
Current in shunt magnet coils	= 5 amperes.
Difference of potential at dynamo terminal	= 100 volts.
Difference of potential at brushes	= 103 volts.
Speed in revolutions per minute	= 620
Temperature of air	= 60° F.
Highest temperature of armature	= 140° F.
Highest temperature of magnet coils	= 125° F.

Electrical Efficiencies.

External electrical power, or "output," available for electric lighting, &c.—

$= C \times E = 108·5\ A \times 100\ V = 10{,}850\ \text{watts} = 89·3\%$

Power absorbed by armature—

$= C_a^2 \times R_a = (103·5)^2 A \times ·04\ \omega = 428·49\ \text{watts} = 3·53\%$

Power absorbed by shunt magnet coils—

$= C_s \times E_s = 5A \times 103V = 515·0\ \text{watts} = 4·24\%$

Power absorbed by main magnet coils—

$= C_m^2 \times R_m = (108·5)^2 A \times ·03\ \omega = 353·17\ \text{watts} = 2·91\%$

Total electrical power—

$(C \times E) + (C_a^2 \times R_a) + (C_s \times E_s) + (C_m^2 \times R_m) = 12{,}146·66\ \text{watts.}$

(Signed) Andrew Jamieson.

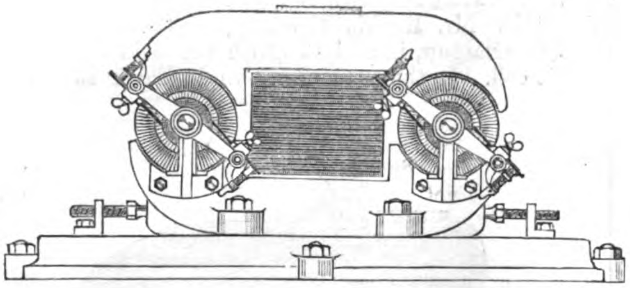

Fig. 3.

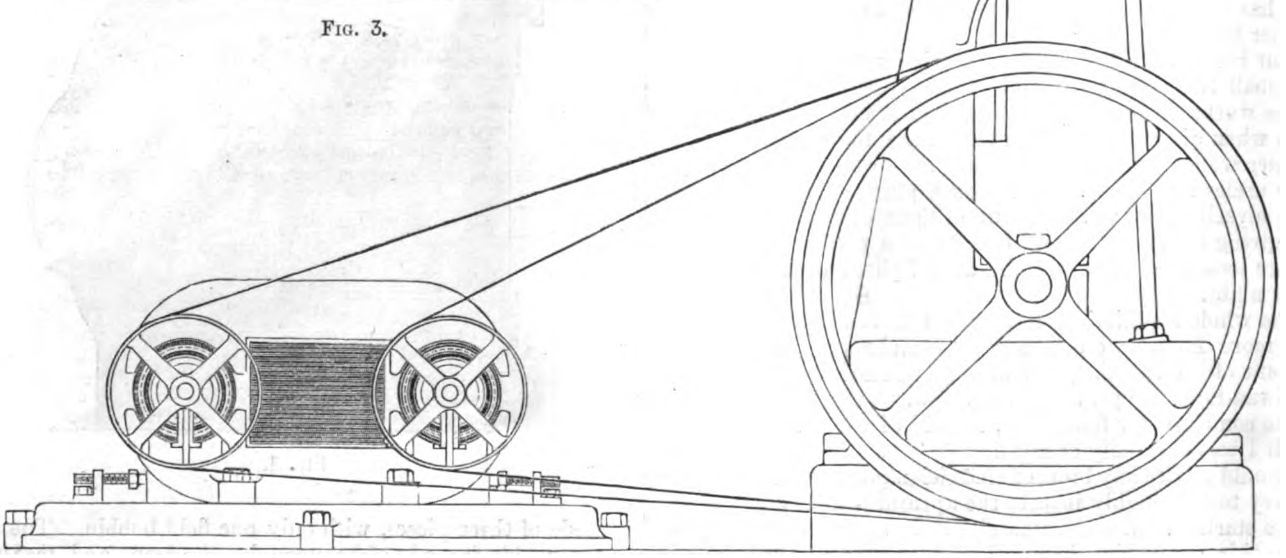

Fig. 2

The peripheral speed of the armature of this machine is only 1,900ft. per minute.

The machine illustrated in Fig. 2 possesses two distinct armatures with one field-magnet. The two armatures may be run together, if desired; but in introducing this machine the makers had more particularly in view to meet the requirement of a spare dynamo at low cost. Their views on this subject are stated as follows:—

"In a ship where space is scarce two dynamos are not often admissible, and a spare armature is invariably carried. Now, this new dynamo is really two complete dynamos in one machine, and the space occupied by the double machine is not more than that taken up by one machine of the best type, and the cost is at least 30 per cent. less than the cost of two machines, being just about equal to one machine and a spare armature. One half of the machine is able to do the whole work, so that repairs may be made on one half of the machine while the other half goes on with the lighting. By adopting a double dynamo

Digitized by Google

all risks of loss of lights through accidents to the running machine are entirely obviated; of course, a spare armature meets the case, but here we have the spare armature in place ready for operation at a moment's notice."

Fig. 3 represents another type of machine with double armature.

IRISH'S ELECTRIC TRAMWAY SYSTEM.

A novel method of conveying current to the trailing collector of an electric tramcar has recently been introduced by Mr. W. E. Irish, of Cleveland, U.S., and seems to obviate some of the most serious objections which have hitherto prohibited the employment of conduit systems upon city lines in this country. It still remains to be seen whether or not the device entails other practical difficulties of an equally serious character; on this point we for the present offer no opinion. Mr. Irish proposes to lay along the centre of the track a third rail consisting of short sections insulated from one another and from the earth. These sections rest upon and are supported by a continuous length of india rubber tubing of oblong or elliptical section, and entirely closed throughout its whole length. Within this tube are a series of flanged contact pieces of copper of T section, the same in number as the sections of the rails. Each contact piece is secured by screws passing through the india rubber to the section of the rail above, so as to secure good electrical connection. At the bottom of the tube the conductor itself is laid, and under normal conditions it is separated from the stem of the T piece by a short space. The trailing wheel of the car is, however, caused to bear upon the upper rail with sufficient pressure to compress the india rubber and to bring the contact piece against the conductor, while as soon as the wheel leaves this section of the rail the elasticity of the rubber again breaks circuit at this point.

The diagram in Fig. 1 will show the arrangement of the parts more clearly.

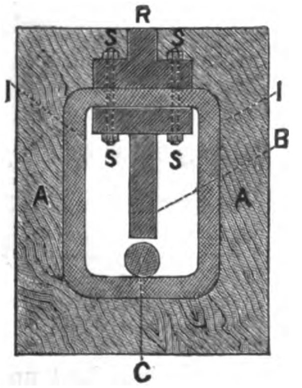

Fig. 1.

A A, Stone or Timber Channel; I I, Section of India Rubber Tube; C, Conductor; B, Contact Piece; R, Rail; S S, Screws connecting Contact Piece with Rail and passing through India Rubber Tubes.

Mr. Irish prefers to use two of these conduits side by side for the positive and negative conductors. He also employs a rotary brush, with stiff wire fibres running in front of the contact wheel, to clear the dirt from the rail.

It will be seen that this arrangement affords perfect security to the conductor, which is completely enclosed along its entire length. The sections of the central rail are also laid flush with the roadway, so that its presence offers no additional obstruction, and from this point of view would appear to be entirely unobjectionable. The danger of short-circuiting by the passage of ordinary traffic over the line is not, however, entirely obviated; in fact, it appears to be somewhat greater in this system than with a slotted conduit. Any heavy vehicle standing across both positive and negative conduits would bring those sections into the circuit; but it is perhaps improbable even than that metallic connection would be established.

The equipment of the car does not, so far as our information extends, present any novel points of special value, though it seems to be of a thoroughly practical and workmanlike description.

AN INDIA RUBBER COMPENSATOR FOR TELEGRAPH, TELEPHONE, SIGNAL, AND OTHER WIRES.

BY R. BOZON.

The severity of the weather this time last year turned my attention to the problem of counteracting its effects upon overland telegraph and telephone wires. My first idea was of a very similar character to that already described in the columns of *The Electrician* by Mr. Caws, of Sunderland, though I was at that time unaware of his experiments. I first employed a steel spring, let into the length of wire, and found that this greatly raised the breaking strain of the combination. It soon struck me, however, that it would be necessary to afford protection from the weather, and I therefore enclosed the spring in a thin brass telescopic case, in which the spring acted upon a piston and rod, fixed to the outer case, and was effectually protected from the weather. The telescopic case, however, considerably increased the weight of the appliance. In order to reduce the weight and cost, I found that the only thing to be done was to make a single case, and to allow the piston rod attached to the spring to pass through a well packed stuffing-box at the end of the case. Even this, however, did not sufficiently reduce either the weight or the cost, and I therefore came to the conclusion that this did not constitute a practical arrangement.

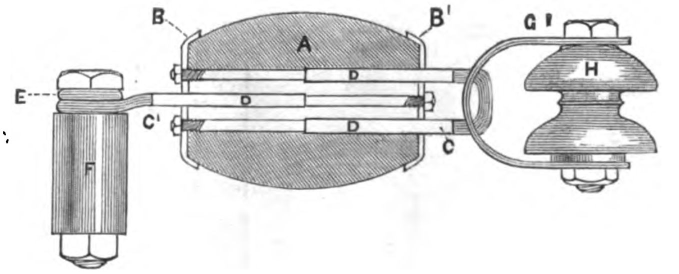

Fig. 1.

A the india rubber cushion between the compressors B and B′, which are maintained in their relative positions by forks C and C′, which are encased where they rub by pieces of brass tube D D D to prevent rusting. E is the loop at the end of fork C′, to enable it to be bolted to part of post F. G the steel band on the end of fork C shackles the insulator H, which is connected to the line.

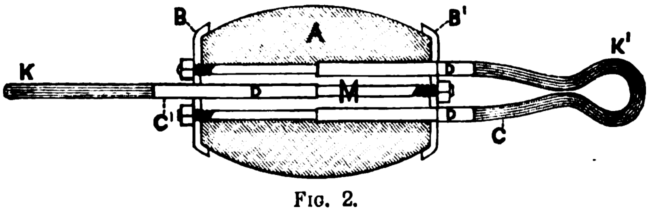

Fig. 2.

This acts exactly the same as Fig. 1, the difference being at the terminals K and K′, which are intended to be joined to the wires, and the currents to pass through the compensators. If the contact is not sufficient, I propose a collector to be attached at M.

Not being willing as yet to allow myself to be baffled, I continued to experiment, and before long was led to try india rubber, and this substance answered beyond my expectation. The form of the india rubber compensator which I finally adopted for telegraph wires is represented in the sectional drawing, Fig. 1, which is sufficiently explained by reference to the lettering.

The elasticity of the india rubber between the compressors B and B′ holds the compressor B′ stationary, while the other compressor B is always more or less in a state of vibration as the stress on the line varies.

Digitized by Google

The pattern designed for use with signal wires is similar to Fig. 2. One of the advantages of this arrangement in telpherage is that it can be applied to any length of line without making a joint; in fact, it is only necessary to remove the shackle, the insulator being left on the line until the compensator is bolted to the post, when the same insulator can be shackled to the other end.

I have found by experiment that with an india rubber cushion, measuring 4in. in length and 3in. in diameter at the widest part, the contraction under pressure reduced the length as follows:—

Pressure.	Length in inches.
0	4
½ cwt.	3¾
1 "	3½
1½ "	3¼
2 "	3
2½ "	2¾

This table could be altered, as found by experiment to be of the greatest advantage, by altering either the quality or thickness of the india rubber.

PATERSON AND COOPER'S AMMETERS AND VOLTMETERS.

I.—Permanent Magnet Instruments.

Permanent magnet instruments have this advantage over many other types of ammeters and voltmeters that they are very dead-beat, and although possessing the defect that they are liable to alteration through the magnet being weakened or strengthened, they are favourite instruments, the demand for them still keeping up. When working with accumulators they are specially serviceable as indicating the *direction* as well as amount of current. These instruments, the original design of which was due to Profs. Ayrton and Perry, have been greatly improved by the makers during the last two years, the interior of the present pattern being shown in Fig. 1. Formerly the different parts of the instruments were independently fastened to the ebonite slab; now all the various parts which must be preserved in the same position relatively to each other are mounted on a strong metal plate, the shape of which is in no way altered by any possible shrinking of the ebonite. The magnet is of horseshoe shape, of steel, with soft iron pole-pieces. The needle is of soft iron, elliptically shaped, and mounted in the coil frame, the pivots moving in jewelled holes. When the instrument is wound the needle is almost completely enclosed by the coil The coil frame with the needle is attached to a bar, which can be moved parallel to the axis of the needle, this adjustment being employed to obtain the proper value for the deflections. As the needle is pushed into the field the value of the deflections increases, reaching its maximum when the axis of the needle lies on a line joining the centres of the poles; withdrawing the needle decreases the value, and the adjustment is made until the instrument is direct-reading. The coil frame is itself capable of movement round the staff of the needle as a centre, the object of this adjustment being to get the magnetic axis of the coil exactly at right angles to the magnetic axis of the magnet, and as a consequence the deflections right and left equal. Besides these two adjustments there is one more to be mentioned. Screwed through each of the soft iron pole-pieces, and slightly protruding towards the needle, is a soft iron pin, by moving which the distribution of the field lines is modified, until the deflections for the whole of the scale are proportional to the current flowing round the coil. These several adjustments are made by the makers, the instruments having, when sent out, a straight line law and reading direct. The ammeters and voltmeters are essentially similar in construction—the winding only being different—and in the voltmeter the terminals smaller. The voltmeters are provided with a spring push to be pressed down when readings are being taken.

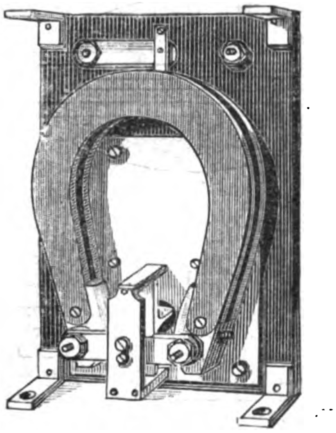

Fig. 1.

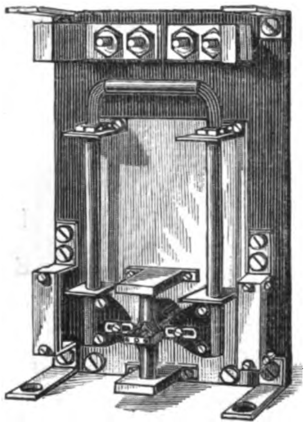

Fig. 2

II.—Electro-magnet Instruments.

For the reason above given that the permanent magnet instrument is liable to error from the strength of the magnet altering, the electro-magnet instrument was introduced, the current to be measured in this type exciting the magnet, and thus furnishing the controlling force. Messrs. Paterson and Cooper were amongst the first to introduce these instruments, but their later forms have been considerably improved, and an interior view of one of the ammeters is shown in Fig. 2. The magnet here consists of a bundle of from 50 to 60 No. 26 charcoal iron wires, most carefully annealed, the ends of which are threaded through a soft iron bent up pole-piece of the shape shown. The needle is of shape similar to that employed for the permanent magnet instrument, and of soft iron. It is mounted in the galvanometer coil frame, and this frame, along with the electro-magnet coil bobbins, is rigidly attached to a strong brass frame. There is no necessity here for right and left adjustment, as the needle only deflects in one direction, and things are so arranged that while the galvanometer coil, magnet coils, and pole-pieces are fixed rigidly in position, the bundle of wires forming the limbs and yoke of the electro-magnet can be slid further through or withdrawn further out of the pole-pieces. This alters the strength of the controlling field across the needle, and the adjustment is made until the instrument reads direct, the magnet being securely fixed in position when the latter is correctly ascertained. On each pole-piece is fastened an adjusting plate, the position of which is altered until the deflections are proportional to the currents flowing in the coils. The instruments have thus a straight line law, and are direct reading.

The workmanship and finish of these instruments are of a high order of excellence, and reflect great credit on the resources of Messrs. Paterson and Cooper's establishment.

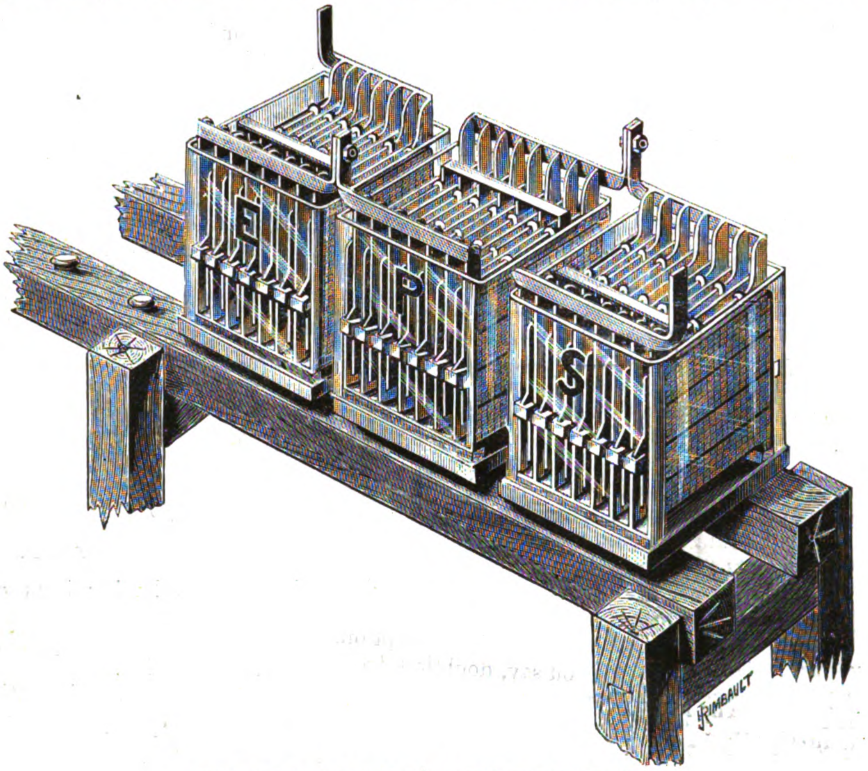
NEW TYPE OF CELL OF THE ELECTRICAL POWER STORAGE COMPANY.

A new type of storage cell which will be issued in future by the Electrical Power Storage Company has been considerably improved in its mechanical detail and arrangement. The containing vessels are larger in order to allow an increase of distance between the opposite plates. This distance is now sufficient to prevent a falling pellet of paste from bridging the gap between the plates. The spongy-lead electrodes are burned together in five places, viz., at the bottom corners (constituting feet on which the section stands), about midway on either side of the plates, and again, at the conducting strip. At the bottom corners a projection is made on the plate which has the effect of raising it, so that there is a space of about 1¼in. clear between the bottom edge of the plate and the bottom of the containing vessel, and, as a result, the powder which may fall cannot deleteriously affect the working of the battery. The peroxide plates are burned together in two places at the conducting strip, and at a carrier strip on the top edge of the plates. They are supported clear of the bottom of the containing cell on insulating saddles, which are carried by the bar which connects the porous lead plates at the side.

The separating arrangement consists of vertical ebonite forks of rectangular section, which give greater rigidity than has heretofore been obtained. There are no glass plates and no indiarubber bands or plugs, the idea being to dispense with any material which can be considered of a perishable nature (the peroxide plates of course excepted). It is believed that as a result of these improvements the battery will be able to work uninterruptedly without attention for at least two years, and that when it requires cleaning after that period the labour involved will not exceed a quarter of an hour for a cell having a capacity of 600 or 700 ampere hours.



THE E.P.S. COMPANY'S NEW TYPE OF CELL.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *Dec. 24th*, 1887.

Attention was recently called to the rapid development of the alternating system in this country in the hands of the Westinghouse Electric Company. The system was exploited first barely a year ago, and the latest reports from the Westinghouse Company are that it has now in use or contracted for a total of about 200,000 lights. It has, all told, about 85 central stations installed or in process of construction, and during the month of November it closed contracts for 22 central station plants, aggregating over 30,000 lights. Street lighting also promises to command considerable attention in connection with this new departure, incandescents superseding ordinary street gas burners. About a score of the Westinghouse stations now supply lights for the streets. The Thomson-Houston Company is also doing a large alternating business, and the Fort Wayne Jenney Company is putting out several Slattery plants of the same character. There is a report current, though it lacks confirmation, that the Westinghouse Company may possibly change its type of alternating machine.

Meantime, there are not wanting evidences that trouble is brewing between the Edison Company and the new combination, which includes the Thomson-Houston Company, the Westinghouse Company, and the Consolidated (Sawyer-Man) Company. The war has already broken out in the Courts, and the fire of the heavy legal artillery is being supplemented by a guerilla system of pamphlets. Aside from the legal question involved, the Edison people take the bold stand—and propose to justify themselves in it—that, as compared with the direct system of distribution, the alternating is by no means as economical, and that the alternating introduces, moreover, elements of danger from which the direct system is conspicuously free. It will not be surprising if the Edison Company comes out with some definite statement on these points, joining issue with those who have claimed such enormous saving for alternating systems now in vogue.

Some very interesting work is to be attempted in New York Harbour in the direction of operating incandescent lights on the buoys there. The first trial is to be made on the Robbin's Reef lighted buoy, whose name has probably become quite familiar to English readers in connection with the International yacht races. A 50 candle-power incandescent lamp will be placed on this buoy, and the contract has already been

Digitized by Google

made for two thousand yards of double conducting cable to connect the buoy with the shore. The experiments will be carried out by the Lighthouse Board, chiefly under the direction of Lieut. Millis.

Figures have just been made up of the work done on the new electrical subways of New York to date, and they are somewhat interesting. The engineer reports a total length of excavation since last July of 129,918ft. Of single duct conduits for telegraph and telephone service there has been laid 903,180ft., and for distribution purposes 4,050ft. There was room for 13,700 miles of wire. Of single duct conduit laid for light and power wires there were 254,210ft., giving a capacity of 2,542,500ft. of wire. In addition to this, which was intended for arc-current purposes, there were 186,745ft. of conduit for incandescent lighting. This is a pretty good record of work; but the Subway Board are experiencing some difficulty in getting the electric spider to bring its web into their parlour. The United States Illuminating Company has brusquely declined to lend an ear to the seductive invitations of the Board, and it seems quite likely that this matter of forcing the electric light companies into the subways will have to go before the Courts for adjudication.

Much interest attaches to the action which the Police Commissioners of this city are about to take in regard to the establishment of a system of electrical police alarm. The commissioners have about $100,000 to spend, and are receiving estimates on a basis of 500 alarm boxes, although as there are already about 1,000 posts over which police jurisdiction extends, it will be seen that the contractor stands to handle not less than about a quarter of a million of the city's money, and doubtless a great deal more. The commissioners are now looking into the merits of the various systems, among which is the well-known Gamewell and the Herzog teleseme, which includes a dial on which are 200 or 300 words and indications. An early decision is expected in the matter. It is said of one of the systems that the Republican Commissioners are inclined to favour it, while the Democratic Commissioners are against it. As such matters ought to be settled entirely on technical and practical considerations, it might seem that politics have nothing to do with the case; but they have. One reason why so much importance attaches to the present decision is that the action of New York is likely to be followed by other cities. The main idea is to have the police at all times in direct communication with headquarters, and wherever this has already been attained its advantages have been manifest.

One of the evening papers here has just published an interesting article, evidently by one who is pretty well informed, on Mr. Edison's "lieutenants"—that is, the men who have shared his confidence and have helped him to bring out and perfect his many inventions. It is interesting to know that one of the most prominent men in the list is Mr. Charles Batchelor, an Englishman who came here some twenty years ago in the employ of the Coates Thread Company, of Manchester, and thereupon formed an acquaintance with the great inventor which has grown more and more intimate as the years roll by. Mr. Batchelor, who is well known in Europe through the hard work he did there in introducing the Edison system of electric lighting, is now giving himself up almost exclusively to laboratory work, and the article mentions the fact that ever since the Menlo Park days Mr. Batchelor has had a contract with Mr. Edison, that has never been reduced to writing, but which is thoroughly carried out, that he is to have one-tenth interest in profits of all the products of the laboratory. The exact manner in which this contract is carried out is unknown, but its existence is highly creditable to the good faith in each other and to the strong friendship of the persons interested. It may be mentioned in this connection that another Englishman who enjoys Mr. Edison's confidence in a marked degree is Mr. Samuel Insull, who has practically charge of the huge Edison Machine Works at Schenectady, where, by the way, is another Englishman, Mr. Phillips, whose brother is a member of the firm of Johnson and Phillips. It might be mentioned, too, that Mr. Edison has just taken into his laboratory **Mr. A. E. Kennelly**, of London.

Americans are generally supposed to be well satisfied with their patent system, but this is hardly the case, although the system is eminently a good one. The lapse of time has brought to notice many points in which it may be improved. The National Electric Light Association, through its general counsel, Mr. Arthur Steuart, has gone so far as to prepare a Bill to appoint a Commission for the revision of the Patent Law, and on Tuesday, December 20th, Mr. Steuart read a paper on the general subject before the American Institute of Electrical Engineers, calling attention in detail to the reforms considered necessary, and to the manner deemed best for securing them. The meeting was a very interesting one, but brought out great diversity of opinion on the subject both in the speeches and in the correspondence submitted. While there was a general desire for various reforms, such for instance as the establishment of a distinct Patent Court, there was felt by some to be danger in urging on legislation at this time, and in placing the whole patent system at the mercy of grangers and others whose influence would be inimical, and could not be despised. Another objection raised by some persons was that it was unwise to agitate the matter in view of the Presidential campaign of next year, when public attention would certainly be riveted on such leading issues as that of Protection *versus* Free Trade. In all probability the Bill prepared, which has already been printed in the electrical journals, will be laid before the Patent Committee of Congress, and will be pushed.

CORRESPONDENCE.

BRADFORD ELECTRIC LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My attention having been called to your article on this subject in your valued journal of the 23rd December, I venture to mention one or two points which, unless corrected, may lead to misconception.

You say, doubtless from information given you, that the corporation and a local company who have effected an installation here have each voluntarily incurred a certain risk—the one by invading the rights of the borough, the other by permitting its rights to be invaded. You add that of the two "we are inclined to think the corporation are most responsible, seeing that by condoning a private installation in the first instance they virtually confessed they had no intention of doing the work themselves."

The fact is that there has not been any invasion of the corporation rights by the company, although once attempted, and, consequently, the corporation have not permitted any invasion. The company carry on business under the Companies Acts without any licence or Provisional Order from the Board of Trade, and therefore free from all the onerous obligations which Government insist upon when they grant a licence or Provisional Order. They knew from the first that the corporation have an Electric Lighting Act, with large powers in addition, under a local Act, for preventing anyone from carrying electric wires over or along any street. The buildings of the company are so situated that they can convey their electric apparatus into several adjoining places of business without crossing any street, and this the corporation cannot prohibit them from doing. The Board of Trade were duly apprised of the proceedings of the company at the end of 1886, but did not feel at liberty to interfere.

At subsequent dates the company applied to the corporation for leave to carry their wires over the streets. This the corporation refused, and the company acquiesced. On one occasion the managers of a leading club contrived to get a cable from the company's works connected with the club across one of the highways, but as soon as the existence of the cable was known the corporation required it to be removed; and this was complied with.

Digitized by Google

The corporation have always contemplated exercising their powers, but the collapse of all the electric lighting schemes in other towns induced the corporation to stay their hand until further experience had been obtained. In thus acting they were guided by the electric engineer whom they consulted, and now that the subject of electric lighting appears to offer more satisfactory results the corporation have determined to establish an installation upon a modest scale, but so arranged as to admit of extension if the measure of success they may attain warrants them in so doing.

I am sure you are anxious to have everything connected with this operation of the corporation accurately stated, and therefore feel it due to you to mention the above circumstances.—Yours, &c., W. T. M'GOWEN, Town Clerk.

Town Clerk's Office, Town Hall, Bradford,
3rd January, 1888.

"MEDICAL ELECTRICITY."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Perhaps my experience of medical electrical quacks is, since you have ventilated the subject, as interesting as any one's.

I was invited by an "eminent consulting medical electrician" to attend a lecture at his rooms, and I accordingly went. The lecturer stood at a small table, on which were belts innumerable and various other wonderful appliances, and also a small motor with a fan mounted on the axis, a bell, and a Holtz machine, all *ostensibly* the invention of this "eminent consulting medical electrician." The first part of the lecture was dull, but showed talent. The lungs were compared to a sponge, various other essential portions of the human frame were discussed, and so forth. At length the electropathic belt was exhibited and described. The belt is worn next the skin; on the inner side of the belt is a series of metal discs, copper and zinc, and we were told that when the salt, moist skin of the body came in contact with the discs, a current of electricity was set up, depending for its strength on the number of the discs. He then proceeded to illustrate this by making the current produced in this way by a belt on his body ring a bell and drive the fan on the motor. This I could not stand, so jumped up and told him that if he intended to convey the impression that such a current could drive a fan in the way described, I knew it was absolutely untrue. I asked him if he had a battery anywhere about him. He was very wroth, and loudly denounced me for interrupting, said *it was not allowed*, and added that I should have every opportunity of examining the apparatus afterwards, and that the "electricians" downstairs would explain everything to me. However, when the lecture was over he promptly vanished, but we found, of course, a large battery under the table.

I then got hold of one of the "electricians" down stairs and cross-examined him, and he assured me the current of electricity produced by the salt skin of the body and the discs was the only current employed by them in their "cures." Before, however, I left, I told him I was an electrician myself and knew that what he said was quite untrue. He then acknowledged that when people came to them for treatment, they were placed in a chair under which was a strong battery, which was then coupled up in some way with the belt. I must not forget, however, to mention that before this confession was made to me, the same "electrician" assured me that the "current" had often been measured by means of an electrometer. I asked to see this experiment, and was told they were sorry to say the electrometer was out of order. I suppose the strong current fried it up.

The most thriving electrical quack establishment I ever saw was in Brooklyn, U.S.A., where they had the most elaborate suite of rooms decorated with gilt, with soft subdued pink lights burning. This establishment sold whole suits of clothes of the "belt" type, and the modest price for a suit was, I believe, $150. The sale was enormous.—Yours, &c.,

J. M. V. MONEY-KENT.

Connaught Mansions Victoria-street, S.W.

THE CENTRAL ELECTRIC LIGHTING STATION AT LUBECK.

(*Translation of a letter in the "Hamburg Correspondent."*)

Let me first give a short history of electric lighting in Lübeck. In February, 1884, the German Edison Company asked the Senate for a license and concession for the supply of electric light for Lübeck. This request was not granted, as the town intended to do the work itself. A committee was elected for the thorough investigation of the matter, and on the 19th July, 1886, the Senate and Council decided, after hearing the report of the committee, upon erecting an electric plant under the auspices of the State of Lübeck. Tenders for executing the work were solicited, and S. Schuckert, of Nuremberg, was given the contract in February, 1887, for the whole plant—dynamos, apparatus, instruments, and cables, and including the connections with the installations of private buildings. It was only after Easter, however, that the contractor could commence with the building of engine and boiler houses. The erection of these buildings, together with the placing of the boiler, the steam engines and dynamos, and the laying of the cables and installations, took a much longer time than was at first anticipated, and the month of August came before the contractor could proceed with the erection of the steam engines, dynamos, and the electric apparatus. Simultaneously with the completion of the whole of the works in the engine house, the cable last put underground was tested. After sundry trials in the engine house and in a small number of private buildings had been made in the beginning of the month, on the 16th of November the whole system was shown in operation, including about 1,000 glow lamps (16 candle-power) and about twenty arc lamps of 600 candle-power, to which exhibition the members of the Senate and Town Council were invited. This first trial, as well as subsequent ones, proved to be a great success, and the plant has shown itself to be well executed in all its details. The whole system was started working on November 22nd, 1887, and has earned the fullest commendation, not only from the knowing ones but from the general public. Originally the plant was only intended for a regular supply for 3,000 glow lamps (10 candle-power) and 100 arc lamps (400 candle-power), requiring 250 horse-power. However, when laying down the plant it was thought better to have a respectable reserve, and also to make provision for the extension of the system by one half. The underground cables were at the same time prepared so as to give sufficient conducting power for the calculated increase.

The engine house and chimney are erected in the centre of the town. The engine house is closely connected with the boiler house. Nearest to the entrance is a single cylinder steam engine, of about 50 horse-power, with a wrought-iron flywheel of three metres diameter. Behind are placed four dynamos of the well-known Schuckert construction. Each dynamo gives a current capable of supplying electricity for 700 16 candle-power glow-lamps. Two more dynamos of the same capacity will be fixed when the installation is extended, the foundations for which extensions have already been laid. For propelling the four dynamos already fixed, two large compound steam engines of 200 horse-power each have been obtained, and each of them is furnished with a flywheel of $3\frac{1}{4}$ metres diameter. Both engines are fitted with condensing apparatus. Along one side of the engine house is placed the common driving shaft, which is driven by the engines by means of flax ropes, the dynamos being driven from the shaft by means of leather belts. The transmitting shaft is supplied with frictional clutches and pulleys, by means of which both the steam engines, as well as the dynamos, can be adjusted at will while the machinery is in motion. Close to the engine house, and separated from it by a wall, is the boiler house, in which are three of Heine's patent water-pipe boilers, manufactured by Borsig, of Berlin. Each boiler has a heating area of 70 square metres. These boilers are in connection with a chimney 40 metres high. On the other side of the engine house, at the same altitude as the dynamos, is placed a most interesting apparatus provided with controllers and regulators, for use not only in making the electric fluid, but for delivering it. From the dynamos are cables bedded under the floor leading to the switch-board, and from thence beyond they lead to two strong copper rails which take the entire current from the dynamos. With the aid of the switch-board the current from any of the dynamos can, while the engines are in motion, be excluded or otherwise, without influencing the remaining dynamos. The pressure, in spite of the occasional occurrence of irregularity in the motion of the engines, is, in a most simple manner, kept at an exactly normal pitch through rheostats. Nine couples of cables branch from the above-mentioned copper rails which directly lead the current to the division centres. Each pair of cables is provided with a current measurer, which indicates the pressure upon it at any time, and also with a regulator, which automatically regulates

Digitized by Google

the current, and keeps it at the pressure required by the consumer. Branch cables lead from the division centres through the streets and supply the electricity throughout the town. Altogether there are about 10,000 metres of lighting cables laid through the principal streets, the diameter of which measures, according to the strength of the current, from 40 to 240 square millimetres. The city of Lübeck is the first in Germany to decide upon constructing an electric central station at its own expense and under its own municipal supervision, and that this step is being recognised as one worthy of imitation may be learnt from the fact that already a great number of towns have followed its example, or are about to do so.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions*

17,905. C. GASSNER, JUN. London. Improvements in or relating to the manufacture of galvanic dry elements. December 29.

17,926. W. E. HAYNE. Safety fuses for electrical circuits. December 30.

17,965. F. REDMOND. Machines for cleaning windows, &c., by electrical power. December 31.

17,966. Y. RHODES. Electric batteries, and applying same to lighting miners' safety lamps. December 31.

18,015. E. J. BERNHEIN. Electrical connection for a number of telephonic stations. December 31.

COMPLETE SPECIFICATIONS ACCEPTED.

NOTE.—*All persons interested in opposing the grant of a patent on any one of the undermentioned applications may, at any time within two months from the dates in italics, give notice at the Patent Office in the prescribed form of such opposition.*

December 31, 1887.

15,344. A. M. CLARK. London. Automatic switch and governor for electric lighting purposes. (The Electrotechnische Fabrik Cannstatt [Wirth and Co.], Germany.) November 24.

16,865. L. R. DAVIES and M. SHEARER. London. Improvements in coupling up batteries for lighting and other purposes. December 23.

PATENTS SEALED.

December 27, 1887.

16,141. J. R. TOZELAND and H. F. TOZELAND. Portable electric call alarm. December 9, 1886.

16,177. J. GRIFFITHS. Denbighshire. An improved form of wind motor for electric lighting and other purposes, and mode of regulating and controlling the machinery driven thereby. December 10, 1886.

4,135A. H. J. HAIGHT. United States. Improvements in electro-magnet clock time transmitters. March 18 1887.

4,303. W. MAIN. United States. Improvements in and relating to secondary and other electric batteries. March 22.

LEGAL INTELLIGENCE.

Pearson v. The Maxim-Weston Electric Light Company.

An action was heard last week in the Glasgow Sheriff Court, brought by Ebenezer Westmoreland Pearson, electrical agent, 23, Wilson-street, Hillhead, against the Maxim-Weston Electric Light Company, carrying on business at Buchanan-street, Glasgow, for £525 in name of salary and damages. After hearing debate, Sheriff Erskine Murray sustained the defenders' plea of no jurisdiction, pursuer having no cite in Glasgow, and found them entitled to expenses, modified to one-third, as he thought that defenders had exceeded their powers in taking possession of pursuer's office and furniture.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 23rd, 1887, amounted to £4,993, and for the week ended December 30th to £4,102.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of December, 1887, was 3,925, estimated to produce £3,300, against 3,695 messages, producing £3,125, in the corresponding month of 1886. The traffic receipts for the month of September, 1887, estimated at £2,500, realised £2,494.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for December, 1887, amounted to £2,004, against £1,782 in the corresponding period of last year.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of December, 1887, amounted to £57,703, and to £52,823 in the corresponding period of 1886.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of December, 1887, amounted to £38,908, and to £40,539 in the corresponding period of 1886.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for December, 1887, amounted to £21,600; from 1st January to 31st December, 1887, they amounted to £264,480; while for the corresponding months of 1886 and 1885 they were £258,600 and £284,720 respectively.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended 31st December, 1887, were £4,300.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 30th December last, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,318.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 31st December, 1887, are £2,826, as compared with £3,089 in corresponding period of 1886. The September receipts, estimated at £4,357, realised £4,453.

CARBON TRADE.—We are requested to state that after 1st January the Globe Electrical and Engineering Company, of 7, Carteret-street, Westminster, will act as sole London agents for the Barnsley Carbon Company, of Barnsley, and will supply both carbon rods and plates from their London stores at the same price and terms as the Barnsley Carbon Company.

We are asked to notify that in future the style of the General Electrical Apparatus Company will be the General Electric Company (G. Binswanger and Co., proprietors).

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 504.—Vol. XX. FRIDAY, JANUARY 13, 1888. Price 4d.

NOTES.

The sixth issue of the Electricians' Directory for 1888, published at this office, is now ready. The present year's edition has been greatly enlarged and improved, both in the matter and arrangement of its contents. Information likely to be of use to the practical electrician, both for the scientific and commercial aspects of his business, will be found in this Directory. Several new and important features have been introduced, adding considerably to the value of the work as a book of reference.

We are at length enabled to announce that an agreement has been arrived at between the United and the National Telephone Companies, whereby the metropolis will shortly be placed within speaking distance of the Midland Districts, and ultimately also with the North of England. A heavy copper line will at once be laid to Coventry, and from there it is intended to fork to the left to Birmingham, and thence to Liverpool and Manchester, and to the right to Nottingham, Sheffield, and Leeds. The details are not yet, however, fully decided upon, but it may be anticipated that the line will be open to Birmingham within a few months from the present time.

The Great Sewage Question is about to be solved once for all by the application of electricity. So the *Standard* announced to the world last Saturday morning; and the Metropolitan Main Drainage Works, which are under process of reconstruction for the application of a chemical process, will of course be stopped until Mr. W. Webster, F.C.S., has perfected his experiments—which, however, from the *Standard's* account, do not appear to have gone beyond the contents of a tumbler or a glass bottle. Mr. Webster's method—or, shall we say, idea?—is to transmit a current of electricity between two metallic electrodes through the sewage, the effect upon which is to suspend the solid matter instead of precipitating it. Had the *Standard's* judgment on this "invention" been first subjected to the same treatment, and with exactly similar results, we should have regarded the scheme more hopefully. Still the facts, as stated, are interesting and even important apart from the sewage question, and we should be glad to learn more about them.

Since writing the above we have ascertained that the experiments referred to by the *Standard* are being carried out on an extended scale, and that no decisive opinion should be formed upon the facts made public by that journal.

Apart from the nonsensical or fraudulent charlatanism with which the application of electricity in medicine is unhappily too often associated, we take it that in a minor degree the scientific development of the subject is retarded by the unscientific way in which it has been handled by qualified medical practitioners. It is difficult for an electrician to study the literature of the subject from his own point of view without some feeling of impatience. We have before us a work of recent date treating of the application of electricity to medicine, written by a medical man whose qualifications in his own department of science are beyond dispute. Yet his book opens with a broad assertion which, though possibly true, has never been scientifically demonstrated. "In its natural state," we are told, "electricity pervades all things, animate and inanimate, throughout nature; *without its invigorating influence all life would become extinct.*" The italics are our own, but the sentence painfully reminds us of the familiar assertion of the advertisements, "Electricity is Life," or, as in a variation we have recently met with, "Electricity is the Physical Basis of Life." A little further on we find that the author has solved to his own satisfaction the vexed question of the seat of E.M.F. in the voltaic cell, and that he is further able to announce that "all molecular disturbance, however excited, must give rise to electrical disturbance." This again is an assertion which we are not so rash as to deny off-hand, but we should be grateful for a somewhat more detailed explanation of the author's proofs on a matter of such profound interest.

Still another obstacle in the path of an electrician who may desire to learn something of the application of electricity to medicine lies in the terminology employed. Of amperes and volts the average medical electrician is, of course, entirely innocent. A favourite mode of indicating resistance is as so many Atlantic cables. The reader is supposed to be overwhelmed with astonishment on learning that the resistance of his own body probably exceeds that of two Atlantic cables. Such terms as "Franklinism" and "Galvanofaradisation" are frequently met with, and are well calculated to alarm the uninitiated. Seriously, however, we do not see why a doctor who writes upon this branch of his profession should not take the trouble to use, so far as possible, both the methods and the language of the electrical profession. He certainly would

Digitized by Google

not compromise his dignity by so doing, and if, as is so much to be desired, the subject is ever scientifically developed, it will surely be by doctors who become electricians and not by electricians qualifying for the medical profession. The Institute of Medical Electricity which Mr. Newman Lawrence proposes to establish, and which is receiving support from some of the leading men in each profession, should, however, go far to remove these complaints; at any rate, it seems to be a step in the right direction.

OUR readers will probably agree with us in thinking that M. Menges' thermomagnetic motor, whose advent we foreshadowed some time since, and which we now describe at length in another column, will at once take rank as the most promising attempt which has yet been made to produce electrical energy from the direct conversion of heat; indeed, so far as we have yet been able to form an opinion, it seems to us to bid fair to bring that long-sought consummation within measurable distance of practical realisation. It will be seen that M. Menges' apparatus differs from Edison's pyromagnetic generator principally in two points, each of which is of very great importance—(1) by means of an adaptation of the well-known experiment of Schwedoff the necessary rotation is performed in an entirely automatic manner; (2) the core upon which the armature coils are wound is *not* subject to variation of temperature. Two of the most serious difficulties which occur in the pyromagnetic generator are thus entirely obviated by M. Menges.

OF course, like every other heat engine, the efficiency of the apparatus will be a function of the difference which can be maintained between the maximum and minimum points of temperature; but in this case the efficiency clearly will not be directly proportionate to this difference, but will depend on the curve connecting the magnetic permeability of the metal with its temperature. According to some old experiments of Rowland, the maximum intensity of magnetisation of nickel at 12° C. is 494 C.G.S. units, and at 220° C. 380 units, while, according to the text-books, at 350° C. nickel "loses its magnetic properties." M. Menges is now engaged in investigating this point, and we hope shortly to publish a complete curve, from which the best working temperatures may be deduced. It will then become a question at what speed the armature should run so as to combine the most efficient conditions of temperature variations with the production of maximum E.M.F. It is evident that the slower the speed the more easily the change of temperature can be effected, and the greater, therefore, the variation in the strength of the magnetic field; but of course the rate of cutting lines by the armature is correspondingly less. All these points will require careful experimental development.

IF both Edison and Menges had not already got machines of this type to work we confess that we should have been inclined to fear that at any moderately rapid speed of rotation a practically uniform temperature would, sooner or later, be arrived at. We are glad to learn that this is not the case.

ONE of the most obvious developments of M. Menges' idea evidently lies in its application to small motors. If permanent magnets are used for the field no wire at all would be required on the armature, and we should have as simple, and, we may hope, as practical an apparatus as could be devised. A steel magnet, soft iron pole-pieces, a nickel "distributor," with an iron ring as armature, and the apparatus would be complete. There certainly appears to be a most promising field in this direction. It may also turn out that a motor of this kind, coupled up with an ordinary dynamo, will prove a more practical method of generating current than the combination of motor and generator in one machine.

As to output, this will necessarily be lower than in an ordinary dynamo; but we must not lose sight of the fact that the comparison of weight of material lies with the dynamo *plus* the engine or other source of motive power. M. Menges is not prepared to give detailed figures on this point at present, but may be expected to do so shortly.

"IT is about time," says our Boston (U.S.) electrical contemporary, yclept *Modern Light and Heat*, "for the 'Electricians' Dictionary' (published by *The Electrician*, London) to appear." We are somewhat at a loss what to make of this observation, particularly when we are further instructed that "copies should reach this office not later than the middle of January." Seeing that we know nothing of a dictionary published at this office, we greatly fear that by the middle of January our contemporary will be sadly disappointed. We can only explain our contemporary's evident misunderstanding on one of two suppositions—(1) the word "Dictionary" is a printer's error for "Directory"; or (2) the reference is to a "Cyclopædia of Electricity" which has been advertised in our columns as a forthcoming publication, but with which we have not and have never had any other connection.

WE can, however, appreciate our contemporary's anxiety to obtain a "dictionary" at an early date, inasmuch as in the same issue we are taken to task for remarking that "the primary battery epidemic had broken out in a severe form in New York." On this we are referred to the scriptural admonition about extracting a mote from a brother's eye, and much is said which must perforce be admitted to be true enough about the extravagances of primary batteryists on this side of the water. But *Modern Light and Heat* evidently fails entirely to appreciate the full meaning of the word *epidemic.* We may mention that the *Electricians' Directory* is now ready.

THE *Progressive Age* states that the house in which Prof. Morse, the inventor of telegraphy, was born is still standing in Charlestown, Mass., an object of very little interest to the passing throng. The residence in which Morse lived at the time of his death in New York City is unmarked, save by a marble slab, about six inches square, set in the front wall, reciting the brief fact of the inventor's death within. Our contemporary continues:—"The world owes so much to that great inventor that it does seem as though there ought to

Digitized by Google

exist a sufficient number of public-spirited gentlemen, who have made vast fortunes out of telegraphy, to gather a fund, which should be used to purchase either or both of these buildings, and instal therein a museum of curiosities denoting the stages of advancement in electrical science."

Garston.—The sugar refinery and docks of Messrs. Bostock and Co., Garston, are to be lighted by electricity. The Lever system is the one to be adopted.

The Commercial Cable Company.—Mr. J. W. Mackay has presented the whole of the *employés* of the Commercial Cable Company with a fortnight's salary as a Christmas present. Needless to say this generosity is highly appreciated.

"Every Man his own Lawyer."—Messrs. Crosby Lockwood and Son send us a copy of the 25th edition of their well-known legal handbook under the above title. This edition has been "reconstructed, thoroughly revised, and much enlarged."

The Anglo-American Brush Company's Almanac. — This company has sent us a handsomely got-up sheet almanac, containing a photograph of a Victoria dynamo, driven by friction gear from a Brush engine. A number of useful electric lighting data are also supplied.

The Royal Victoria Hall, Waterloo Bridge-road, S.E.—The January lecture arrangements at this hall are as follows:— Tuesday, January 17th, F. W. Rudler, Esq., F.G.S., "Caves and Cave Men"; Tuesday, 24th, Prof. Bonney, F.R.S., "The Oldest Monuments in Brittany and Britain"; Tuesday, 31st, Prof. Ramsay, "Speech made Visible, or Picture Writing as it was and as it is now."

Obituary.—We regret to record the death of Mr. George Henley, M.S.T.E. and E., and brother of the late Mr. W. T. Henley, of North Woolwich. Mr. Henley died on the 8th inst. at his residence, 47, Drayton-park, Highbury, N. We regret also to record the death of M. Raynaud, of the French Telegraph Service, who, as reported in our last issue, was shot at and wounded by an assassin. M. Raynaud was forty-four years of age.

An Electrical Railway Transfer Table.—At Chicago a transfer table, weighing about 15 tons, in the shops of one of the railway companies, has been fitted with an electric motor of 7½ horse-power. Power is derived from a dynamo at a distance of 750ft. The tractive resistance of the table when loaded with a Pullman car is about 1,500 pounds. The gearing is of a somewhat elaborate description, but is said to work very well, and its manipulation is quite simple.

Telephone from House to Dynamo Machine.—Lord Armstrong, whose dynamo machine is situated some 700 yards from his house, has connected the two by means of a telephone. We are informed that a pair of A type "Swinton" telephones, supplied by the Equitable Telephone Association (Limited), are employed, and though the telephone line runs quite close and parallel to the electric light wires throughout the entire distance, the induction is not sufficient to cause any inconvenience.

The German Telegraph Service.—The German Post-Office is this year expending some £375,000 additional for the telegraph and telephone services, of which the latter gets about £150,000. In Berlin and Hamburg the wires are going underground at a cost respectively of £75,000 and £25,000. Copper is now used on all new lines. Multiple trunks are to be erected between Cologne and Frankfort, Berlin and Dresden, Berlin and Frankfort, and Berlin and Cologne. These are estimated to cost £41,000 odd, while £5,000 is to be devoted to altering existing iron and steel lines to copper.

Arc Lamps and Alternating Currents.—At his first juvenile lecture on "The Application of Electricity to Lighting and Working," given to a crowded audience at the Society of Arts, on Wednesday evening, the 4th inst., Mr. W. H. Preece, F.R.S., showed, for the first time in public, an arc lamp fed by alternating currents from a central station. The lamp used on this occasion was a "Brockie-Pell," and the bright, white light given was steady enough to please the most critical eye. The current was supplied by the Grosvenor Gallery station, which is over a mile away from the society's hall.

Newcastle Exhibition Awards.—We understand that the list of awards published by the Exhibition authorities was confessedly preliminary and incomplete, and that several awards, through incomplete description of the article or imperfect statement of the feature for which the award was made, have not yet been published. Among these there is at least one of considerable interest to electrical engineers, which has been withheld for the present on account of its appearing in more than one class. It is expected that these awards will be finally confirmed at the next meeting of the council.

Another Westinghouse Enterprise.—A company called the Overhead Conductor Electric Railway Company, of Pittsburgh, of which Mr. G. Westinghouse, jun., is president, has just been organised, and announces that it has acquired patents of Joseph R. Finney for supplying electricity to moving vehicles by means of travellers upon overhead conductors. The circular goes on to say that after a thorough investigation these patents are believed to cover the entire right to use such appliances, and legal proceedings will be taken against all infringers. Licences may be obtained at the uniform rate of $250 per car.

Temporary Lighting.—The occasion of the annual ball given to the staff of Thorpe Asylum, near Norwich, on the 6th inst., was this year made especially agreeable by the lighting of the hall by the means of four 200 candle-power incandescent lamps. The motor, driving one of Messrs. Paris and Scott's C type No. 2 dynamos, was a new rotary engine brought out by Messrs. Sturgess and Towelson, of Norwich. Motor and dynamo were coupled together and bolted to a cast-iron bedplate 3ft. by 2ft., running 1,300 revolutions per minute. The light was noticeably steady, and the hall remained cool, even at the early hour of three in the morning.

Nottingham.—The application of electric motors to small industries is effectively illustrated in the show room of the Wheeler and Wilson Company, in Nottingham, where a number of sewing machines are shown at work, driven by a half horse-power Immisch motor, receiving its current from a dynamo in one of the factories about 200 yards distant. The work has been carried out by Mr. W. B. Sisling, late electrical superintendent of the Newcastle Exhibition, and great interest appears to be taken in the little motor by the spectators. We compliment the local manager of the Wheeler and Wilson Company on his enterprising display, and have no doubt that it will lead to business both in sewing machines and motors to drive them.

An Automatic Chess Recorder.—Messrs. Woodhouse and Rawson have on view at their show rooms an ingenious apparatus, devised by Dr. Wurstemberger, of Zurich, for obtaining an automatic record of the moves upon a chess-board. The

Digitized by Google

pieces are provided with stems fitting into holes at the centres of the squares, and in so doing a contact is closed which, through the medium of a relay, actuates a type-printing wheel by which the index number and letter of the square from and to which the piece is moved are recorded. By an ingenious arrangement the moves of the black pieces are recorded on a different part of the tape from those of the white. This is accomplished by making the pegs of the white pieces entirely of wood, while the black pieces carry a metal stud which closes a contact and shifts the wheel laterally. A good deal of ingenuity and skill have evidently been devoted to the apparatus, and we understand that it is anticipated that a far more extensive field of usefulness will be open for its application than that for which it has ostensibly been designed.

Paris.—The Paris Municipal Council has passed a resolution authorising the expenditure during the current year of one million francs for the establishment of a municipal central lighting station to supply electricity for lighting the Hotel de Ville and the surrounding district. The details of the scheme are not yet decided upon, but it is understood that the machines will be placed in the Rue des Halles, and would light the Hotel de Ville, the Markets, the Place du Chatelet, and the Avenue Victoria.—The Council have also recently issued a set of regulations to be complied with by companies undertaking the distribution of electricity. Underground cables are insisted upon. Licenses will be granted, without conferring monopoly, for a period of 18 years. The maximum rate of charge to be permitted is fixed at 6 centimes per carcel hour, or 60 centimes per (French) horse-power-hour. The company is to be liable to a tax of 100fr. per annum for each kilometre length of conductor, and 10 per cent. upon its gross receipts. The city has the right of buying out the company at the end of five years.

Snyers' Clutch Pulley.—M. Raymond Snyers, of the Louvain University, has designed a novel clutch which appears to possess some valuable properties. It consists of a disc, carrying on its face a large number of short wires, set vertically; these wires catch upon projections, set in the pulley, to which the disc is opposed. The clutch is thrown in or out of gear by a movement which shifts the disc nearer or further from the pulley, or *vice versâ*. In a clutch 21¼in. diameter, and capable of transmitting 26 horse-power at 100 revolutions, the number of wires employed is 14,400. Each of these wires is deflected at its extremity to the extent of two millimetres, and exerts a power of about 50 grammes, or less than one ounce. A clutch of this type, 11in. in diameter, has recently been fitted to a shaft, transmitting motion from a six horse-power Rajot petroleum engine to a Gramme dynamo in a shop at Brussels. The dynamo runs at 1,500 revolutions, but the engagement and disengagement are said to be effected instantaneously with very little pressure.

An Electrical Type-Setting Machine.—Messrs. S. Capehart, S. G. Goodson, and C. L. Redfield, of Minneapolis, have designed a machine, actuated by electricity, for setting type, or rather for making a matrix from which casts can be taken. The letters are punched into a strip of cardboard the width of a column, from which a stereotype is made in exactly the same manner as stereotypes are now made from pasteboard matrices. The work of punching the dies in, of feeding in the cardboard, and of preparing it for the next stroke is all done by electricity. The operator simply has to push the die plate to the right place and strike the key. Mr. Redfield, who thinks the invention will create as much of a revolution in printing as Gutenberg did, points out that the application of electricity to the work opens up a field the wideness and novelty of which makes it difficult of comprehension. For instance, he says there is nothing to hinder a press agent in Chicago from sitting down to his machine and simultaneously making matrices on similar machines in Minneapolis and St. Paul, Milwaukee, Kansas City, and Omaha. One man operating the electro-matrix machine will supplant at least five men setting type.

Vienna.—The Vienna correspondent of *Industries* states that the Imperial castle at Laniz, which is situate in the middle of magnificent forests, was some time ago partly fitted with a glow lamp installation. This has proved so successful that the Emperor has ordered an extension of the installation, so that every room in the castle may be lighted by electricity. The total number of glow lamps to be fixed amounts to about 1,000. An extension of the installation in the Vienna Town Hall has also been resolved upon by the municipal authorities, notwithstanding the fact that the working cost of the existing installation was found very much higher than originally estimated. The installation at the Vienna Opera has been thoroughly examined and found in perfect order by two officers of the Vienna Technological Museum. Prof. von Waltenhofen is now engaged in an examination of the internal arrangements of the electric light installation of the Court Theatre, especially as regards the insulation resistance of the circuits. This installation will be suppled with current in the same way as the Opera House, from the Central Station in the Schenkenstrasse, but will not be ready before spring.

The Electric Light in Spanish Theatres.—In our issue of November 18th, we referred to a proposal to make the use of the electric light compulsory in Spanish theatres. We now learn that tenders are invited at the Ministry of Finance, Madrid, for the supply of the electric light in the Teatro Real. The full conditions are given in the *Industria é Invenciones*, a Barcelona technical journal, of December 31st. We may state briefly that the conditions provide that incandescent lamps shall be used in the body of the theatre, and arc lamps, under certain restrictions, on the stage and outside the building. Satisfactory provision must be made for obtaining absolute certainty of light, non-explosive generators, silent machinery, a supply of light equal to the maximum produced by gas, the necessary combinations and suitable machinery for easily and safely producing the desired scenic effects, &c. The installations for the stage, for the body of the theatre and exterior, and for the other parts of the building, will have to be separate, and the installation must be exclusively for the theatre. Three months are given for the presentation of proposals, and the light is to be definitely ready for use on the 1st September next.

Early Days of the American Telegraphs.—The *Electrical Review* of New York says that "The talk of a new telegraph line between New York and San Francisco has aroused the old timers in New York to lively reminiscences of the building of the first line across the plains. One pole, 100 miles west of Laramie, was set up four times, and each time hacked down by Indian tomahawks. Each time there was a bloody skirmish with the redskins for temporary possession of the stump. At last the pole was given to a young man who is now high up in the management of the Western Union. He laid a mine in the hole, set up the new pole, trailed the fuse to an ambush of rocks close by and waited with two armed friends. Then a band of eight Sioux came along and held a war dance around the pole. When the mine was fired all but three were killed and those three carried off Minie balls with them. The powder blew up the pole again, but it cleaned the hole out nicely for a new one, which was thereafter let alone. This story was told with great *éclat* at Del-

Digitized by Google

monico's, and was the signal for more bottles and more stories. It is curious what enthusiastic story tellers are to be found among New Yorkers who have seen life in the Rockies."

Electric Communication with Lightships.—At the monthly meeting on the 6th inst. of the Hastings Town Council, the Corporation, in conjunction with that of Ramsgate, adopted the following memorial to the Queen:—"To the Queen's Most Excellent Majesty,—May it please your Majesty—We, the Town Council of the borough of Hastings, desire most respectfully to approach your Majesty, and to represent the great importance of electric communication between the lightships of the Goodwin Sands and the shore, and also between the 'Sovereign' lightship and Eastbourne, being carried out as speedily as possible. The recent sad disaster to the German emigrant ship off Dover has deeply impressed us with the dangers attending the navigation along this perilous coast and crowded seaway, and we would respectfully submit that the proposals we are now advocating would materially lessen the dangers, and prevent in a great measure the sad loss of life at sea to which our attention is so frequently and painfully directed. We venture to bring the matter before your Majesty thus earnestly, well knowing your Majesty's deep and constant sympathy with all classes of your Majesty's subjects, and your Majesty's anxiety to alleviate the sufferings of the distressed."

Bournemouth.—A scheme has been set on foot at Bournemouth for the utilisation of the waste heat of the furnaces of the refuse destructor employed by the Town Commissioners for the supply of electric light. Mr. W. Lynd, in a paper communicated to a local journal, estimates that 30 horse-power will be available from this source. A report has also been prepared for presentation to the Commissioners by Mr. G. R. Andrews, the town surveyor. It is proposed to lay down engines and dynamos for the direct supply of twenty-five 3,000 candle-power arcs, to utilise the power during the day-time to charge accumulators for the supply of incandescent lamps. We understand that the E. P. S. Company are preparing an estimate for the latter portion of this scheme. It further appears that the Town Commissioners have recently ordered two 9 horse-power gas engines for pumping sea water to supply the street water-carts, and as these engines will usually be available for at least 12 hours per day in the summer and much longer in the winter, it is proposed as an alternative scheme to employ them for the same purpose. Mr. Lynd, who seems to have taken up the question with the utmost enthusiasm, concludes his paper with some excellent advice as to the necessity for having the work, if done at all, done thoroughly well, and to remember that the lowest tender is not always the most satisfactory.

The Electrical Distribution of Time.—In a paper recently read before the Paris Académie des Sciences M. Cornu has shown analytically that to obtain synchronism in a vibrating system the necessary and sufficient condition is that the free motion of the system shall be a damped vibration, and has also pointed out that the stable condition is obtained more rapidly the greater the amount of the damping. To carry out this in practice it is necessary, if two pendulums are to vibrate synchronously, that they should experience an impulse in one direction, and a retardation in the opposite sense in rigorously the same way. This M. Cornu obtains by fixing a permanent magnet to the lower extremity of the pendulum, the magnetic axis being perpendicular to the axis of the pendulum. An electro-magnet, with open circuit, is fixed on one side of the pendulum, and attracts it at each oscillation. On the other side is placed another electro-magnet, with a closed circuit, which acts simply as a damper and checks each swing. In this way perfect synchronism can be obtained between clocks a very considerable distance apart, which, indeed, is only limited by the length of line at which the retardation of the current from self-induction becomes sensible. Clocks constructed on this principle for the Geographical Department of the French War Office have been successfully synchronised over a distance of forty miles of a defective telegraph line.

Chelsea.—Rival Electric Light Companies.—At the last meeting of the Chelsea Vestry, the surveyor said he had received a letter from the Chelsea Electric Supply Company (Limited), and had been handed a letter which Mr. Mossop had received from General Webber, and his answer thereto. He reported that the point of this correspondence practically is as follows:—"That the Vestry is not in a position to grant the Cadogan Electric Light Company leave to place wires in, over, across, or along any street in Chelsea, because of the monopoly held by the Chelsea Electricity Supply Company. The latter company has appealed to the Board of Trade in support of their contention. As the interests of the Cadogan Electric Light Company are more affected than those of the Vestry, it may be that they would prefer to be directly represented at the hearing of the appeal. He therefore recommended the Vestry to (*a*) refer the letter to the Electric Lighting Committee, with power to act, and (*b*) to appear before the Board of Trade to defend the action of the Vestry, and (*c*) also with power to confer with the Cadogan Electric Light Company, and to take any steps with them in this matter as the committee shall decide.—Mr. Mossop moved the adoption of the report.—The Hon. C. Dillon seconded the motion. The Vestry were always thankful to Mr. Mossop for his action in the electric light matter, and they were very fortunate to have so able a man as Mr. Mossop to take an interest in this question, and anything he did the Board would agree to.—Mr. H. Young supported the motion. He thought the Vestry should be glad they could not agree to a monopoly; for his part he should like to see a little competition, for then they would have a chance of getting electric light cheap.—The motion was carried.

Automatic Danger Signal for Railways.—By an arrangement devised by Mr. Drummond, the locomotive superintendent of the Caledonian Railway, the use of fog signals on railways may be dispensed with. An angle bar is placed inside the rail, the one end being fixed to a stud, while the other is raised into position by a lever, worked at the same time as the arm of the signal when placed at danger, or lowered in the same manner when the signal is placed at "clear." On the engine of a passenger train is placed a lever, and the moment that lever comes in contact with the angle bar inside the rail at the signal it disengages another lever connected to a vertical rod, which is put in motion by a spring, and this puts on the continuous brake and stops the train. It requires no action on the part of the driver, as he has no power over the action of the lever. The moment his train stops, the driver knows there is danger ahead, and he waits for information before he proceeds. The apparatus can be applied to any continuous brake, and can therefore be used on all our railway systems without delay. In the case of a mineral or goods train on which there is no continuous brake, the lever is connected with an electric bell, which is rung at once and continues to ring till the lever is again put into gear. The ringing of the bell warns the driver that the signal is against him, and he at once shuts off steam and applies the brake and brings his train to a standstill. A very similar arrangement was brought out some twelve months ago by the station-master at Wimbledon, on the London and South Western Railway, but we have not heard whether it has been practically employed.

THE RISE AND PROGRESS OF TELEPHONY IN THE UNITED KINGDOM.

(Continued from page 50.)

In our last chapter we completed the story of the successful defence of the Bell patents in the case of the United Telephone Company *v.* Harrison, Cox-Walker and Co. We have now to turn to the Edison patent, upon which the plaintiffs claimed the exclusive right to the employment of transmitters combining a diaphragm with the use of carbon. It was in delivering judgment upon this point that Mr. Justice Fry laid down the famous judicial definition of a diaphragm as "something which separates something from something else," a definition which, however otherwise unobjectionable, manifestly embraces, jointly and severally, the sum total of the material objects of the universe.

The Hunnings transmitter, which the plantiffs complained of as an infringement, has been already fully described in the course of these papers (see *Electrician*, August 26th, 1887, p. 338), where also we have already considered its relation both to the discovery of Hughes and to Edison's inventions. At this point we shall therefore confine ourselves to a brief recapitulation of the arguments set forth at the trial for and against the view that the instrument constituted an infringement of the Edison patent. Our readers will recollect that the Hunnings transmitter consisted of carbon in the form of powder loosely enclosed between two metallic plates.

In order fully to understand the position it is necessary to recognise the fact that Edison's claims were essentially for a *combination* of known parts. He did not, for instance, claim the use of carbon in order to vary the resistance of the circuit by its compression, for Clerac had already employed a tube filled with carbon, which could be more or less compressed by a screw in order to obtain a continuous adjustment of resistance. Nor did he claim the use of a method whereby the resistance of a closed circuit could be continuously varied in accordance with the variations of the sound waves, for Graham Bell had done this with more or less success in 1876 by means of electrodes dipping to a variable extent into a conducting liquid. Nor, finally, did he claim the employment of a diaphragm *per se*, for according to the definition already quoted, which was propounded by a witness for the plaintiffs, and upheld by the judge, it is evident that it could not be denied that diaphragms had been employed by previous experimenters. The gist of Edison's claims lay, in fact, in the *combination* of a diaphragm with carbon electrodes in such a manner that the electrical resistance of the circuit through the electrodes varied continuously with the phases of the vibration of the diaphragm, the combination being for the purpose of transmitting articulate speech.

The defendants endeavoured, however, to set up a distinction between a variation in resistance due to changes of pressure upon the carbon and a variation due to an increase or diminution in the number of points in contact. Upon this question the evidence of Sir William Thomson clearly had great weight with the judge. Sir William stated in cross-examination that he was "strongly of opinion that the cause [operating in Edison's instrument] was the change of area of contact." This view had been strengthened by some experiments of his own. We may quote this passage from the evidence for the sake of its own intrinsic interest. "I experimented 25 years ago," said Sir William Thomson, "on copper and iron, and found exceedingly minute changes [in electrical resistance]—changes of a fraction per cent., changes comparable with the change of length of the wire. I have experimented upon the resistance of contact, which is the thing in question. It is carbon contact which is so notably effected by these changes. And I have experimented upon metals to find what the nature of the effect was upon which depended the peculiar quality of carbon in being greatly influenced by these changes of pressure. My opinion has long been that it is the difference between a contact of a mere point and contact over an area which makes so great a difference in the whole resistance. But if that difference depends at all in the conductivity of the resistance, it must be felt, though in a less degree, in metal. I have experimented on copper and brass. I experimented more particularly on copper—copper globes, or half globes, solid, and on a rigid copper plate; and I find that when carefully cleaned and pressed together I get a definite resistance between the two, tested by wires soldered to the two plates about two or three tenths of an inch from the small surface of contact. I find that when I apply pressure and increase the pressure I get a continually diminishing resistance; when I reduce the pressure I get a continually increasing resistance. There is a difficulty in obtaining definite numerical results, but I have no doubt from what I have seen that the effect depends wholly on the area of the interface between the two; the effect would be greater than that in carbon [? greater *in* carbon] because of its semi-conductive power."

The witness was next asked whether the brass or tinfoil disc between which the carbon powder was placed in the Hunnings transmitter played any part save that of conducting the current to the carbon. Sir William replied that it also performed the function of conveying pressure to the carbon. The question touched the very core of the matter in dispute, and the value of the patent ultimately depended entirely upon the view taken by the Court upon this point. The following conversation ensued:—

Mr. HEMMING: Suppose you took that foil away, and only got the means of carrying the electricity into a heap of coke carbon, would not the instrument work just as well without the foil?—No; this would not work at all.

Look at this. You see two plates of brass, which are connected with two different poles of the battery?—Yes.

They are some little distance apart, and over the gap is a heap of our coke carbon?—Yes.

Do not you suppose that would speak?—I think very likely.

Just as well as ours?—I do not know whether as well or not.

That is the nearest approach we can make to a Hunnings in principle, with something which shall perform the conducting functions, but without anything which anybody can pretend to be a tympanum. The current goes from one brass plate to the other through the little fragments of charcoal, and of course there is a good deal of resistance in the passage. The amount of that resistance is varied, not by a tympan acting on the charcoal at all, but by the air waves themselves acting. The air waves themselves joggle the little bits of charcoal about and alter the number and nature of the points of contact and so alter the resistance. That is the way it must act in that, and what I am putting to Sir William is—

Mr. Justice FRY: You say this might speak although it has no tympanum?—Sir WILLIAM THOMSON: It has a tympan, my lord.

Where is the tympan?—The tympan is that large surface which you are looking straight at; the top surface of the wood and brass.

The joint?—The top surface of the wood and brass is put into a state of vibration. That increases and diminishes the pressure of every particle of carbon upon the metal. I tried an experiment which I very well remember. It was placing little two-legged or three-legged objects upon the sounding board of a piano, and when the piano was played they all danced. That is the telephone now in court, the result being due to the motion of the platform on which the whole stands.

Instead of there being a direct pressure by the coke or other surfaces above, this would operate by this board moving like the board of the piano and setting in motion the minute particles of carbon?—Yes, clearly, my lord, that board is the tympan.

Mr. HEMMING: I quite follow you, Sir William, and I will not ask you any more about that.

Other evidence in support of Sir William Thomson's view was adduced—notably that of Dr. John Hopkinson. In delivering judgment, Mr. Justice Fry dealt with this vital point as follows:—

"In Hunnings', the up-and-down motion produced by the voice is communicated through the foil to the particles directly; in Edison's, the up-and-down motion of the voice is translated into circular nodal ripples in the disc or tympan. This is re-translated, so to speak, to the centre, into an up-and-motion which is communicated to the cork, and which the cork communicates to the foil, and the foil to the air. The result appears to be that that action in Hunnings' is more accurate, because more direct. In Hunnings' case there is not that magnifying of the operation of the voice that takes place in the presence of the tympan or disc in Edison's. The Hunnings transmitter appears to me, therefore, to be an improvement on Edison's patent; but it may none the less be an infringement of it, and I have come to the conclusion that, like Edison's, it is the combination of a diaphragm vibrating with the voice, that being the platinum foil, with a tension regulator consisting of a semi-conductive

Digitized by Google

resilient and compressible substance, and it is therefore within the scope of Edison's specification.

"It has been argued that Hunnings' transmitter acts on a different principle to Edison's, that the one demands compression and the other freedom of motion; that in the one the presence of the diaphragm is essential, and that in the other it is not; but the evidence, amongst others, of Prof. Dolbear, shows that the presence of the foil is essential or useful in both cases. In both cases it acts as an electrode, in both it requires extension in order that an electric current may pass through all parts of the substance which constitute the tension regulator; in both it keeps the enclosed substances in their places. Before passing from this subject, and considering the meaning of the word diaphragm, I think it not immaterial to observe that Mr. Hunnings, acting with the assistance of the patent agent, whose name he mentioned to us, in describing his own invention, described the top of the platinum foil as a vibrating diaphragm.

"That is exactly the conclusion which I have drawn, that the platinum foil is a vibrating diaphragm, and I have concluded that Edison described as the essential requisite of his invention the combination of a vibrating diaphragm with a tension regulator.

"The discovery Prof. Hughes made in 1878 that the vibrations produced by the voice might operate on a heap of particles directly and without the intervention of any diaphragm or tympan, or any such thing, has, in my opinion, suggested the argument that Hunnings' and Edison's transmitters operate on different principles; but not only is it the fact that the Hunnings transmitter is not used without the platinum foil, but it has not been shown that it can be so used with success, and according to the evidence of Prof. Silvanus Thompson, the same physical principle, namely, that of diminishing the resistance and increasing the current by the increase of contact from pressure, underlies the light of the tension regulator of Edison and the microphone of Hughes."

The Hunnings instrument was therefore held to be an infringement of Edison's specification.

The defendants, however, gained a temporary victory, the objection that the patent was invalid owing to the inclusion of the phonograph in the same specification being upheld. This, however, being a mere error on the part of the agent, the plaintiffs were very properly permitted to disclaim that portion of the specification, and the patent has ever since been fully sustained.

(To be continued.)

THE MENGES THERMO-MAGNETIC GENERATOR AND MOTOR.

We have received from M. Menges (of the Hague) a most interesting description of an apparatus on which he has been at work for some time past, with the object of generating electricity by the direct conversion of heat, or, as it might be more accurately described, by a more direct conversion than that of an ordinary dynamo. M. Menges' apparatus depends, like that of Edison, upon the fact that the magnetic metals lose their magnetic permeability at a certain temperature. It differs greatly, however, from its predecessor in important points, especially in the fact that it does not require the aid of any external source of motive power.

In Edison's pyro-magnetic dynamo it will be remembered that it is necessary to provide some small amount of motive power from an extraneous source in order to revolve the shield by which the heat is alternately directed on one half or the other of the armature cores. M. Menges' apparatus is, on the contrary, wholly automatic.

We proceed to give a free translation of the description furnished us by the inventor.

In attempting to employ the thermo-magnetic properties of iron or nickel in the construction of machines for the generation of electricity upon an industrial scale, we are met with the difficulty that the heating and cooling of large masses of metal not only involves great loss of heat but also requires much time; hence to obtain a useful effect of any importance it would appear necessary to employ machines of dimensions altogether impracticable. By the device and method of construction now to be explained this difficulty has, however, been completely overcome.

The action of a magnetic pole diminishes so rapidly with the increase of distance that it may suffice to remove the armature to a distance relatively small compared with its own dimensions, or with those of the magnet, in order to reduce

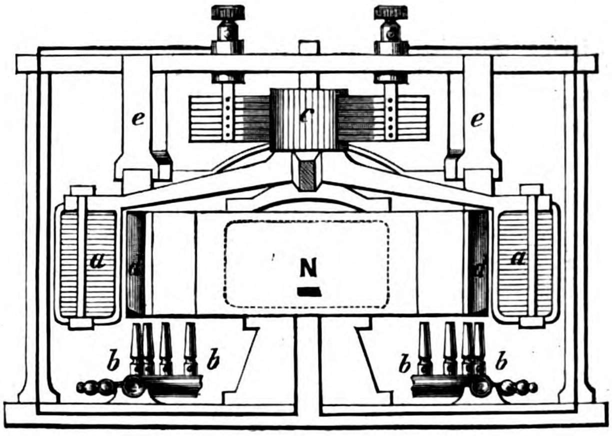

FIG. 1.

the action to a negligible value. But if, the magnet N S and the armature A being at a certain distance, we bring between them a piece of iron or nickel, *d*, then the magnetic force upon A is immediately and very considerably increased. In modern language, the resistance of the magnetic circuit has been reduced by the introduction of a better magnetic conductor, and the number of lines of force passing through A is proportionately increased. The mass of the piece *d* may, moreover be relatively small compared with that of N S and A. If *d* be

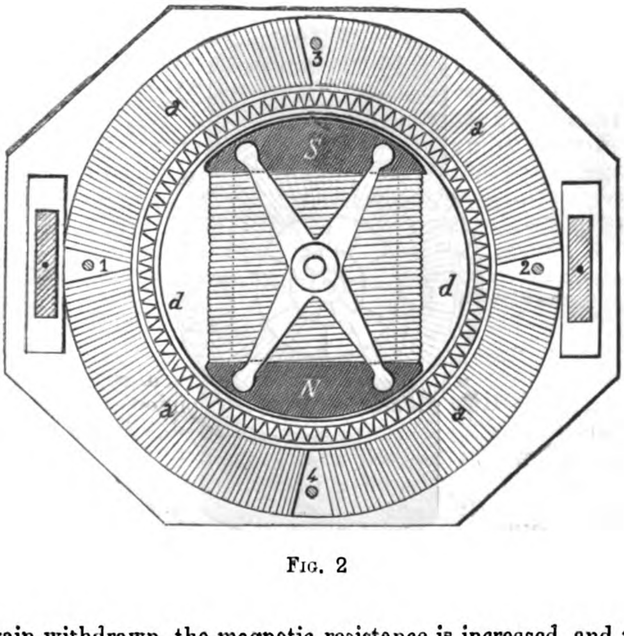

FIG. 2

again withdrawn, the magnetic resistance is increased, and the lines through A are again a minimum.

Now, it is evident that we can also obtain the same effect by sufficiently heating and cooling the intermediate piece *d*; and again, with a broad field we can alter the distribution of the lines at will by heating or cooling one side of this piece or the other. For this reason we will call the piece *d* the *thermo-magnetic distributor*, or, briefly, the distributor.

We will now describe the manner in which this principle

Digitized by Google

has been realised in the practical construction of both a thermo-magnetic generator and motor.

Fig. 1 shows an elevation and part section of one of the arrangements employed. Fig. 2 is a plan of the same machine (in the latter the ring *a a* appearing on a higher plane than it actually occupies).

N S is an electro-magnet, *a a* the armature, wound as a Gramme ring, and fixed to a frame with four arms, which can turn freely upon a pivot midway between the poles. The cross arms of the frame are attached at 1, 2, 3, 4, Fig. 2. Between the magnets and the armature is placed the distributor *d d*, where it occupies an annular space open above and below. Both the magnets and the armature are coated on the sides facing the distributor with mica, or some other non-conductor of heat and electricity. The distributor is attached to and supported by the cross-arms, so that it turns with the armature.

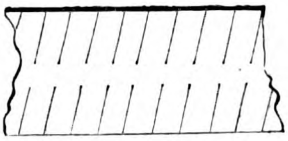

Fig. 3.

The distributor is composed of a riband of iron or nickel, bent into a continuous zig-zag. This form has the advantage of presenting, in the cool part of the distributor, an almost direct road for the lines of force between the poles and the armature, thus diminishing the magnetic resistance as far as possible. At the same time the Foucault currents are minimised. To the same end it is useful to slit the riband, as in Fig. 3; this also facilitates the folding into zig-zags.

The distributor is heated at two opposite points on a diameter by the burners *b b*, above which are the chimneys *e e*. The cooling of the alternate section is aided by the circulation of cold air, which is effected by means of the draught in the chimneys *e e*. At the points of lowest temperature a jet of air or water is maintained. The cross-arms are insulated with mica or asbestos at the points where they extend from the armature to the distributor.

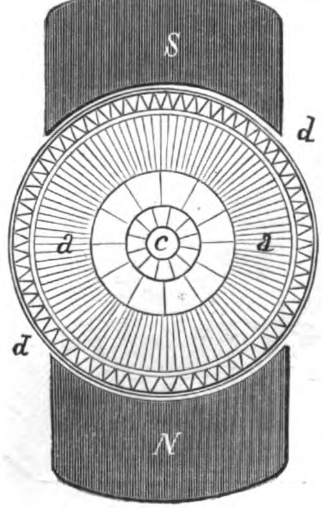

Fig. 4.

It will now be evident that while the distributor is entirely cool many of the lines of force pass from N to S without entering the armature core; but if heat is applied at the points 1 and 2 in the figure, so as to increase the magnetic resistance at these points, then a great portion of the lines will leave the distributor, and pass through the armature core. Under these conditions, so long as heat is applied at two points equidistant from N and S, we might, if we so pleased, cause the armature to be rotated by an external source of power, and we should then have an E.M.F. generated in the armature coils—that is to say, the machine would work as an ordinary dynamo, and the power expended in driving the armature would be proportionate to the output.

Suppose next that the points of heating, and with them the alternate points of cooling 90deg. apart, are shifted round about 45deg., so that the two hot regions are no longer symmetrically situated in respect to each pole of the field. The distribution of the magnetisation has therefore become unsymmetrical, and the iron core is no longer in equilibrium in the magnetic field. We have, in fact, the conditions of Schwedoff's experiment upon a larger scale, and if the forces are sufficient to overcome the frictional resistance a rotation of the ring ensues in the endeavour to restore equilibrium. The regions of heating and cooling being fixed in space, this rotation is continuous so long as the difference of temperature is maintained. The ring in rotating carries with it the armature coils, and of course an E.M.F. is generated in the same way as if the motive power came from an external source. In this respect the machine therefore resembles a motor-generator, and the rotation is entirely automatic.

The armature coils are connected with a commutator in the usual way, and the field may, of course, be excited either in shunt or in series. M. Menges says that the residual magnetisation is sufficient in his machine to start the rotation by itself.

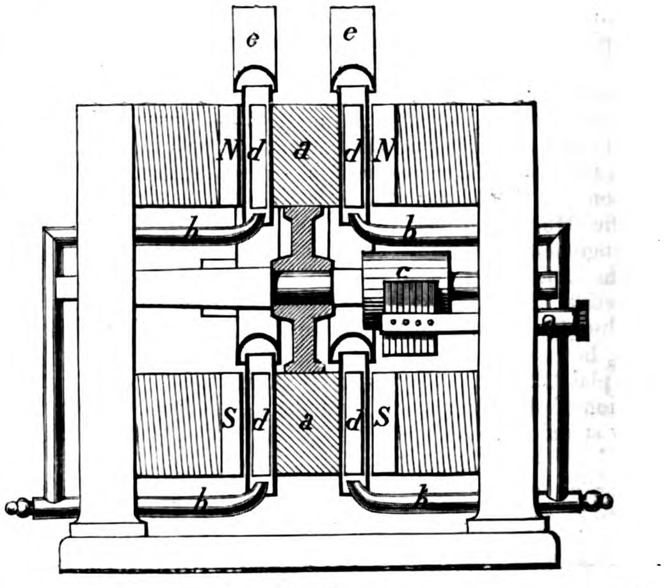

Fig. 5.

When the machine is to be used as a motor it is evident that the windings on the armature core need only be sufficient to supply current to excite the field, or by the use of permanent magnets they may be dispensed with altogether.

M. Menges has further designed a large number of variations on the original type, varying the arrangement of the several parts, and employing armatures and fields of many different types, such as are already in use for dynamos.

In Fig. 4 a machine is represented in which the field is external to the armature.

In Fig. 5 we have a thermo-magnetic generator, which corresponds to the disc machine in dynamos. Similar parts are indicated by the same letters in each of these figures, so that no further detailed description is necessary.

In another modification M. Menges proposes to rotate the burners and leave the armature and distributor at rest. But in this case it is evident that the E.M.F. produced would be much less, because the magnetisation of the core would only undergo a variation of intensity, and would nowhere be reversed, except, perhaps, just in front of the poles. In machines modelled on the Brush type it is evident that the distributor need not be continuous.

Enough has, however, been said to indicate the extent of the field upon which the principle may be applied.

SOME ENGLISH CENTRAL LIGHTING STATIONS.

III.—SHEFFIELD.

The accompanying illustration shows the plan of the central station of the Sheffield Electric Light and Power Company. The company commenced operations in November, 1886, with a 40 arc-light Thomson-Houston 6-ampere plant. The results were sufficiently encouraging to warrant the early enlargement of the station and the introduction of three 50 arc-light 10-ampere Thomson-Houston machines. Good prices are realised for the lights, which are readily taken up by consumers. Three consumers take 30 lights between them, and the lights are used in stores, clothiers', drapers' and hosiers', billiard rooms, cafés, hotels, music saloons, theatres, &c., so that further developments may be looked for at no distant date.

It is needless to add any details as to the working of this installation, the Thomson-Houston system being so well known to our readers. We therefore simply remark that in the hands of Messrs. Tasker the result obtained is fully up to the usual high standard of excellence of this system.

The introduction of incandescent lighting by secondary generators is also contemplated. A Phœnix dynamo is employed to charge storage batteries for the supply of incandescent lights to the offices of the company and adjoining works and premises.

We may add that the same firm has put down a fair number of isolated plants in the Sheffield district. Of these the most important is that now in use during the building of a small-pox hospital which has unhappily become a necessity. The building is being erected in an out-of-the-way district called Redmires, on the borders of the Derbyshire moors, and is to be finished within thirty days of the time of commencement. The work is therefore being carried on day and night without intermission by the aid of a Thomson-Houston 40-light plant.

(Continued from page 215.)

CHAPTER VI.—*Current Indicators (continued).*

59. Now if we intend the coils to be joined electrically in series a little thought will show that the coils must be wound

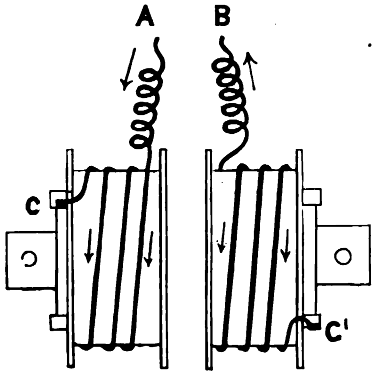

FIG. 22.

opposite ways. Referring to Fig. 22, each coil when its winding was commenced had the underneath end soldered at C C' to the bobbin, the winding on each coil then being in opposite ways. If now a current is sent, say from terminal A to B, it will flow round the two coils in series and in the same direction through each, the points C C' being connected through the brass work.

If we required to reduce the resistance of the coils, still utilising both, we should connect them in parallel or multiple arc, their combined resistance being then reduced to one quarter

Digitized by Google

(para. 41). To do this we could not alter the connections of the coils in Fig. 22 without having wires between them to connect them electrically. The inside end of either coil, say that end attached to C_1, would have to be removed and connected to the outside end of the other coil, a short wire, *w*, being used if the inside end exposed was too short (see Fig. 23). Then the outside end of the first named coil would have a wire connecting it to the brass work at any convenient point, say at C_2. Now, passing a current from A to B, it is seen to flow through both coils in "parallel," and in the same direction through each, and meet at the brass work C C_2, whence it passes to B.

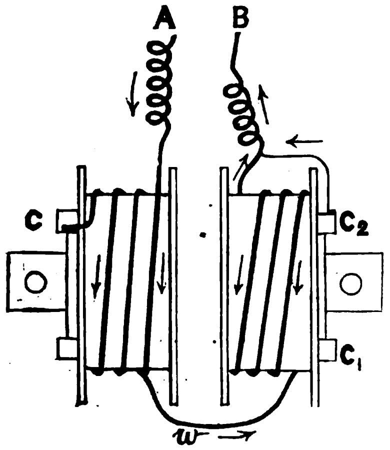

Fig. 23.

If, when the coils were being wound, they were intended to be used in parallel, we should solder both inner ends to the brass frame, as before; but the coils would be wound the *same way*, their outer ends joined together forming one terminal, A, and the other terminal, B, being a connection simply to the brass framework (see Fig. 24). It will then be seen that the current traverses both sides simultaneously and in the same direction.

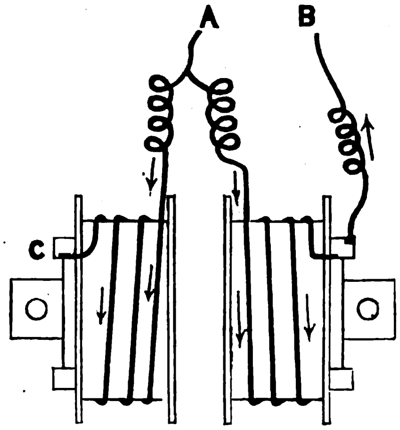

Fig. 24.

60. The resistance of the coils is an important point as regards the sensitiveness of the instrument when we come to employ it with batteries of different resistance. For instance, any number of similar voltaic cells connected in series would give the same deflection on the detector as a single one of those cells if their internal resistance was high and the resistance of the instrument coils very low. No idea could be formed, therefore, from such a test as to the number of cells connected together.

To take an example—a Minotto cell (see para. 17) measures when in actual work about 1 volt E.M.F., and 20ω internal resistance. Now, if we connect this to a low-resistance detector—say $\frac{1}{10}$ω—the current through the instrument will be $\frac{1}{20 \cdot 1}$ ampere, or 49·7 milliamperes; and if we connect ten of those cells in series the current will be $\frac{10}{200 \cdot 1}$ ampere, or 49·9 milliamperes. Now, as the current is practically the same in the two cases, the deflections on the instrument will be equal, and therefore we should be unable to tell from the indication of the instrument alone what battery power was on.

If, on the other hand, the resistance of the coils was higher, say 100ω, we should get with one cell $\frac{1}{20+100}$ ampere, or 8·3 milliamperes, and with ten cells in series $\frac{10}{200+100}$ ampere, or 33 milliamperes—*i.e.*, about four times as much current, and therefore a sufficient difference in the deflections.

Similarly, if low-resistance batteries connected in multiple arc were tested with a high-resistance detector, the deflection would be the same for any number of cells. As an example, take large size bichromate cells which will measure about 2 volts E.M.F., and 1ω resistance per cell, and let the detector coils measure 100ω. One cell connected to the instrument would give $\frac{2}{1+100}$ ampere, or 19·8 milliamperes; and ten cells in multiple arc would give $\frac{2}{0 \cdot 1+100}$ amperes, or 19·9 milliamperes, and therefore there would be no difference in the deflection.

On the other hand, if we emply a low-resistance detector, say one of $\frac{1}{10}$ω, one cell would give $\frac{2}{1+0 \cdot 1} = 1 \cdot 82$ ampere, and ten cells in multiple arc $\frac{2}{0 \cdot 1+0 \cdot 1} = \frac{2}{0 \cdot 2} = 10$ amperes, giving considerable difference in the currents, and therefore in the deflections.

61. Speaking generally, therefore, we should conclude that the more nearly the resistance of the detector coils approximated to the internal resistance of the batteries tested, the more sensitive the instrument would be. We must, however, go further than this, and see what are the exact relations of the resistances for maximum sensitiveness.

When we pass a current through a coil of wire we set up inside, and in the space immediately surrounding that coil, what is termed a "field of force." The physical properties and delineation of this field will be considered more in detail subsequently, but for the present it will suffice to say that this field resembles that surrounding a permanent magnet, and exerts a turning force on any pivoted magnetic needle in the centre of the coil, tending to draw it into a line parallel to the axis of the coil. The actual *force* exerted on the needle depends as much on the strength of the needle poles as on the strength of the field created at the point where the needle is placed—in fact, is the product of these two factors. The stronger the field of force created in the coil the larger the deflection of the needle will be. We have therefore to consider what should be the conditions of winding and resistance of the coils to give the strongest field when any source of E.M.F., such as a battery of known resistance, is employed to send a current through it.

Now the strength of field produced at the centre of a coil varies as the strength of current, also as the total length of wire wound on, and inversely as the square of the mean distance of the wire from the needle, or if the coil is circular and the needle suspended at its centre, inversely as the square of the mean radius.

62. Suppose now that the size of the bobbins and the space to be occupied by the wire when wound on has been fixed upon; then the strength of magnetic field of the coils will vary simply as the product of the current through them and the square root of their resistance. The latter will be clear on considering that for a given weight or volume of wire the resistance is proportional to the square of the length. As an example of this, if we have two lengths, A and B, of different sized wire, B being ten times as long as A, but weighing exactly the same, it is clear that the sectional area of B must be $\frac{1}{10}$ that of A. Since B is ten times the length, its resistance would also be ten times that of A if it was of the same size; but since it is only

$\frac{1}{10}$ the area of A, its resistance is increased tenfold more, and therefore B measures 100 times the resistance of A—in other words, the resistance varies as the square of the length when the weight or volume is constant or conversely, the length varies as the square root of the resistance for a given weight.

63. We have then, as above, the field of the coil proportional to

current × length of wire, for which we may write

$$\frac{\sqrt{\text{resistance of coil}}}{\text{sum of resistance of circuit,}}$$

the current being inversely proportional to the total resistance of the circuit (viz., battery, leading-wires, and detector coil), with a constant E.M.F. This expression for the field can be easily shown mathematically to become a maximum when the resistance of the coil is equal to the battery and leading-wires, but it can be shown equally as well graphically without the aid of mathematics by the plotting of a curve from a few worked-out values. For instance, let us see how the field varies for different resistances of the detector coil when the total resistance *outside* the detector is 100ω.

Taking the resistance of coil as 9ω the field will be

$$\frac{\sqrt{9}}{100+9} = \cdot 0275,$$

and taking it successively as 49, 81, 100, 121, 225, 324, 400, and 484 (these numbers having simple square roots), we find the field becomes respectively ·047, ·0497, ·050, ·0497, ·046, ·0424, ·040, ·0376. These numbers are not in any particular units; they simply give the *relative* strengths of field. Multiplying each by some large number, say 500, will not alter their relation to each other, and will give us whole numbers instead of fractions, which is more convenient for plotting the curve. They will then become respectively 13·7, 23·5, 24·8, 25, 24·8, 23, 21·2, 20, and 18·8.

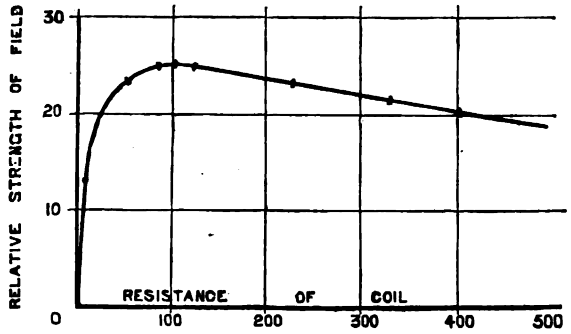

FIG. 25.

Marking off these values on the vertical ordinate (see Fig. 25) and the corresponding resistances given to the detector coil on the horizontal ordinate, we get the curve shown, which indicates that the best resistance for the coil is 100ω, *i.e.*, the same as the resistance of the rest of the circuit.

The curve shows also that if the actual resistance is any given fraction of the best resistance, say $\frac{1}{4}$, the field is the same as with the same multiple of it, viz., four times, both of which in this case give a field of 20. Or a 10ω coil detector would give the same deflection as one wound to 1,000ω for the same size of coil, but the field would only be (by reference to the curve) $\frac{15}{25}$, or $\frac{3}{5}$ of the maximum.

The above figures are all supposing 100ω in the circuit besides the instrument coil, but the curve will necessarily be of the same shape for any resistance taken, and will always show the field, and therefore the deflection, to be greatest when the coil (of given size and given weight of wire) is equal in resistance to the rest of the circuit.

64. For telegraph work, where comparatively high resistance batteries and instruments are met with, the resistance in a detector circuit when used for a battery or line test is more frequently over 100ω than under; they are therefore mostly used from about 200 to 500 ohms. But occasionally much lower resistance batteries require testing, such, for instance, as Thomson's tray cells or Fuller's bichromate cells, when a lower resistance coil, say of 5 or 10ω, will be more sensitive. Some detectors are wound with two coils of widely different resistances for this purpose.

65. A portable detector, the size of an ordinary watch, has recently been brought out by Messrs. P. Jolin and Co., of Bristol, which is wound with two coils, one of fine wire measuring 200·6ω, and the other of thick wire being 0·65ω. There are two bobbins which are first wound with the fine wire coil, the underneath end of the wire being soldered to the frame, and the upper end attached to one terminal, marked Z (see Fig. 26). To use this high resistance coil alone, therefore, the battery wires must be connected, one to the outside case of the detector, and the other to terminal Z, the winding being so arranged that the needle points towards Z when it is connected to the zinc pole. The thick wire coil is wound on next, one end being soldered to the brass bobbins as before, and the free end taken to the other terminal. If we connect the battery wires then between this terminal and the case the thick wire coil alone is in circuit. It would really only be the low-resistance coil that we should require to use alone; when the high-resistance coil was required we should use both coils

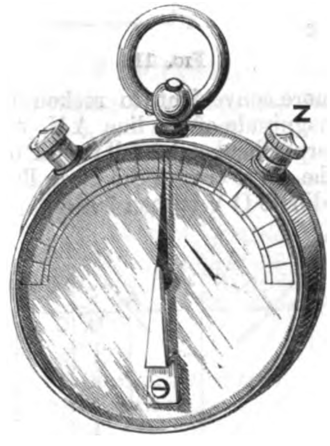

FIG. 26.

in series by connecting the battery to the two terminals, by which we should get the advantage of the extra turns of wire and an inappreciable increase in resistance.

(To be continued.)

NOTES ON ALTERNATE CURRENTS.

BY J. A. FLEMING, M.A., D.SC.

(Continued from page 30.)

In the last notes explanation was made of the analysis of any single valued continuous function into a series of simple harmonic functions. To simplify language we shall in future speak of a curve whose equation is of the form $y = A \sin x$ as a *simple periodic curve*, and if such curve graphically represents the continuous variation of the flow of electricity past any section of a conductor, or the fluctuation of electromotive force in any circuit, we shall speak of such as a *simple periodic current* or a *simple periodic E.M.F.*

Any other mode of variation of these quantities which, graphically represented, would be a single valued curve repeating the same form, will be spoken of as a complex-periodic curve, current, or E.M.F., and, by the foregoing analysis, a complex periodic function can be analysed into a sum of simple periodic functions.

The following method affords a very easy means of drawing a simple periodic curve. Take a cylinder or tube of pasteboard (see Fig. 11) and cut it through obliquely. The section of this cylindrical tube by an oblique plane will be an ellipse. Slit the tube open along the line A B and unfold it. Lay it down on another sheet of paper and draw a pencil line guided

Digitized by Google

by the curved edge A Y Y′. Draw a dotted line, X X′, so that its vertical distance below the highest point Y on the curve is equal to its vertical distance above the points A and Y′, or make O Y equal to A X. Then move this cardboard template forward through a distance equal to its own width, and draw another piece of curve repeating the first and similarly placed (see Fig. 12).

The resulting curve is a simple periodic or simple sine curve. The distance X X′ equal to the circumference of the tube or to the width of the template is called the *wave length.* The distance O Y of the highest point above the mean line is called the *amplitude.* If the bottom edge of the template is divided into 360 parts or units, then the distance O M, measured in such units, of the foot of the perpendicular let fall from any point P from O is called the *phase* of the point P.

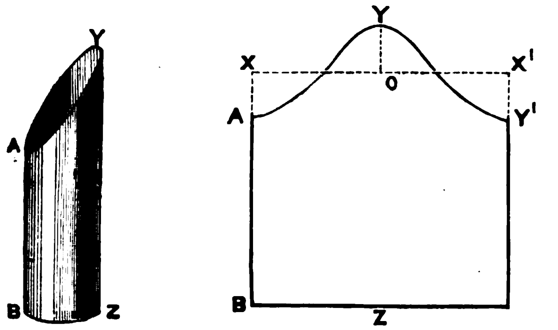

Fig. 11.

It is perhaps more convenient to reckon the phase of the point P by the magnitude of the line A N, or the distance of the foot of the perpendicular, let fall from P on X X′ from the point A, where the curve crosses the mean line. The phase of the maximum ordinate O Y is then 90deg.

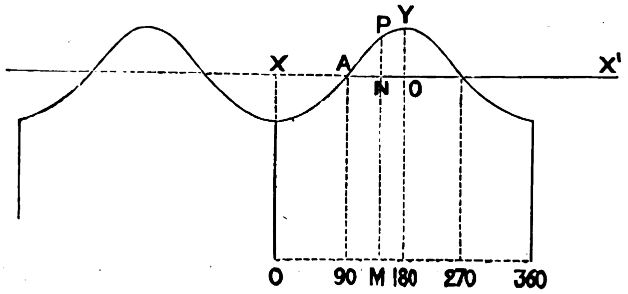

Fig. 12.

Let Fig. 13 represent the semi-wave of a simple periodic curve, we shall proceed to prove some geometric properties of such a curve. Considering this curve as bounding an area of which the other including line is the datum line X X′, we shall first find the value of the mean ordinate. Let X X′ be divided into equal and very small intervals, such as N N′, of which the length is dx, and let X N be called x. Assume as a unit of length the radius of the cylinder, of which X X′ is the semi-circumference. At each of these small elements raise ordinates, such as P N, to touch the curve. We require to find the mean value of all these equi-spaced ordinates when they are infinitely close. The mean value of a number of

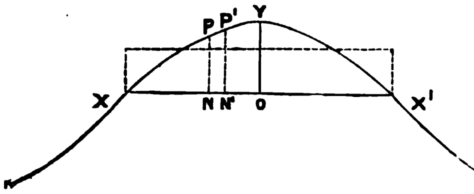

Fig. 13.

things is the sum of them divided by their number. If y denote the length of one such ordinate P N, and Σy the sum of all such ordinates when ruled at n equal and exceedingly small intervals, each of length dx, then the average value of these infinitely numerous ordinates is

$$\frac{\Sigma y}{n}, \quad \text{or} \quad \frac{dx\,\Sigma y}{n\,dx}, \quad \text{or} \quad \frac{\Sigma y\,dx}{n\,dx};$$

but the sum of all such quantities is $y\,dx$, or P N . N N′, is the sum of all the areas of the little rectangular slips into which these infinitely numerous ordinates divide the area bounded by the curve and X X′ and $n\,dx$ is the length X X′, hence we have

$$\text{mean ordinate} = \frac{\text{area X Y X}'}{\text{length X X}'}.$$

The area X Y X′ is obtained by integrating the equation to the curve. Calling the maximum ordinate O Y A, and the distance X N x, the unit being the radius of the cylinder of which X X′ is the semi-circumference, we have

$$y = A \sin x$$

as the equation to the curve, and

$$\int y\,dx, \qquad \text{or } A\int \sin x\,dx$$

between the limits O and π is the area of the curve.

But $$A\int \sin x\,dx = -A \cos x,$$

and this between the limits O and π is equal to 2 A. On the same scale the length

$$X X' = \pi.$$

Hence, the average value of the infinitely numerous and equi-spaced ordinates is $\frac{2A}{\pi}$, or the average ordinate $= \frac{2}{\pi}$ × the maximum ordinate.

The value of $$\frac{2}{\pi} = \cdot 6369.$$

Hence, average value of the ordinate of a simple periodic curve, or the true mean ordinate is ·6369 of the maximum ordinate, and therefore if a current or an electromotive force varies according to a simple periodic law, the true mean current or the true mean E.M.F. is ·6369 of the maximum current or E.M.F. during the phase.

We have here made use of one simple integration, and it is generally easier to master the elements of the infinitesimal calculus than to construct or follow proofs which aim at avoiding its use. We shall, however, indicate how the value of this mean ordinate may be found from first principles. If we call the length of the base line X X′ l, and divide it into n, equal and very small parts of length δx, then $n\,\delta x = l$. Erect at each interval an ordinate whose height is y, then the equation to the curve is $y = A \sin \frac{\pi}{l} x$, where x is as before the distance X N. The mean value M of the ordinate is the sum of all the values of the ordinates divided by their number, or is equal to $$\frac{1}{n}(y_1 + y_2 + y_3 + \&c.)$$

$$\therefore M = \frac{1}{n} A \left\{ \sin O + \sin \frac{\pi}{l}\,\delta x + \sin \frac{\pi}{l}\,2\,\delta x + \ldots \right.$$
$$\left. + \sin\left(\frac{\pi}{l}\,\overline{n-1}\,\delta x\right)\right\}$$

The sum of the sine terms in the bracket is known by trigonometry to be equal to

$$\frac{\sin\left(\frac{\overline{n-1}}{2}\,\frac{\pi}{l}\,\delta x\right) \sin \frac{n}{2}\frac{\pi}{l}\,\delta x}{\sin \frac{\pi}{l}\frac{\delta x}{2}}.$$

Hence $$M = \frac{A}{n}\left\{\frac{\sin\left(\frac{n-1}{2}\,\frac{\pi}{l}\,\delta x\right) \sin \frac{n}{2}\frac{\pi}{l}\,\delta x}{\sin \frac{\pi}{l}\frac{\delta x}{2}}\right\}$$

which may be otherwise written—

$$M = \frac{A}{n\,\delta x}\,\frac{l}{\pi}\,\frac{\frac{\pi\,\delta x}{l}}{\sin \frac{\pi}{l}\frac{\delta x}{2}} \left\{ \sin\left(\frac{n\,\pi\,\delta x}{2\,l} - \frac{\pi\,\delta x}{2\,l}\right) \sin \frac{n\,\pi\,\delta x}{2\,l} \right\}$$

When n becomes infinite, and δx becomes zero, $n\,\delta x$ remains still equal to l; hence in the above expression in this case reduces to the following:—

Digitized by Google

$$M = \frac{A}{\pi} . 2 . \sin^2 \frac{\pi}{2} . = \frac{2}{\pi} A.$$

for the value of $\frac{h}{\sin \frac{h}{2}}$ is 2 when h becomes zero.

Accordingly the mean value of the ordinates when they are infinite in number and equi-spaced is $\frac{2}{\pi}$ times the magnitude of the maximum ordinate.

ERRATA.—In the previous article, Nov. 18, 1887, the reader is requested to make the following corrections :—In Fig. 8 the letters $M_1 M_2$ and $F_1 F_2$ should be interchanged, the upper pulleys being the fixed ones. In Fig. 9, lower diagram, the point B should be diametrically opposite to A, as they are the traces on a horizontal plane of the sides A C B D of the frame A B D C.

(To be continued.)

LEGAL INTELLIGENCE.

The Anglo-American Telegraph Company (Limited) v. La Compagnie Francaise du Telegraphe de Paris a New York.

This was an action brought in the Tribunal of Commerce of the Seine for the purpose of compelling performance by the French company (known as the Pouyer-Quertier, or P. Q. Company) of the pooling agreements made in 1880 and 1882 by them with the Anglo Company, the Direct Cable Company, the American Cable Company, and the Western Union Company. By these agreements all the companies agreed to put their gross receipts from transatlantic cable messages into a joint purse, and divide them in agreed proportions, the share of the French company being 16 per cent. The concession of the French company stipulates that the company shall not amalgamate or fuse their interests with any other Atlantic cable company without the express consent of the French Government in writing. When the first pooling agreement was made with the French company in 1880 they submitted a copy of it to M. Cochery, then Minister of Posts and Telegraphs, and asked for his consent to the agreement. After considerable delay M. Cochery told M. Pouyer-Quertier verbally that the agreement did not require his consent. Consequently the companies put the agreement into execution without the consent being obtained, and it had full execution to the knowledge of the French Government until 1882, when the Western Union Company's cables were brought into the pool and a fresh agreement (precisely similar as regards the fusion clause to that of 1880) was made. No application to the French Government for its consent to the agreement was considered necessary. This agreement was carried out by all parties up to 31st December, 1886, when, without warning or notice, the managing director of the French company wrote to the other companies that M. Granet, the Minister of Posts and Telegraphs, had notified him that the agreement of the French company with the other Atlantic Telegraph Companies was in contravention of their concession, and must be discontinued, and they consequently declared the agreements at an end as from that day. This sudden and startling action on the part of the French company was doubtless brought about by the change which a few months before had been made on the Direction of the French company. Count Dillon, the manager of the Commercial Cable Company, is reputed to have obtained control of the majority of the shares and turned out the old board, putting in a new set of directors assumed to represent in some sort the Commercial Company's views, especially as to raising the tariff, which then stood and still stands at 6d. per word. The Anglo-American Company commenced their action against the French company in the month of February, 1887, claiming performance of the agreements of 1880 and 1882, notwithstanding the alleged Ministerial decision of M. Granet, and 5,000fr. a day as damages until performance of the agreements was resumed, with 5,000fr. a day for every day elapsed since 31st December, 1886, when the agreement was broken.

The case came on for hearing before the Tribunal in Paris on the 12th December last, and was then ably argued by M. Ernest Caron for the Anglo-American Company, and by M. Liquereux for the French company. The argument lasted the whole day. M. Caron argued that M. Granet, as Minister of Posts and Telegraphs, had no right or power to annul the decision of his predecessor, M. Cochery; that the agreement did not require Government sanction ; that M. Granet's letter was not a binding judgment on the question ; that the French company ought to have appealed (as their concession enabled them to do) to the Council of the Prefecture of the Department of the Seine and to the Council of State against M. Granet's decision ; that until a proper and legal decision had been given against the validity of the agreement, the French company were bound to fulfil its conditions, and that they had not acted *bonâ fide* in putting an end to the agreement. M. Liquereux's defence for the French company was, in effect, that the agreement was unquestionably a fusion of interests, forbidden by the concession without the Government's written consent, and that all the parties to the agreement were so advised at the time by their lawyers ; that, although (as he submitted) M. Cochery had verbally said the agreement did not require the Government consent, this was not given in writing and was not binding on his successor ; that M. Granet had in exercise of his right decided that the agreement was contrary to the concession ; that the French company would forfeit their concession if they did not comply with the Minister's requirements—in short, that it was a case of *force majeure.*—The French company had no alternative but to denounce the agreement, and had only acted in protection of their own existence.

On the 9th January, 1888, the Tribunal pronounced its judgment, which is that the French company must resume performance of the agreement from the day of service of the judgment, under penalty of 5,000fr. (£200) a day for every day's delay until the expiration of one month, when the Court will adjudicate upon future damages, and that by way of damages for the past the French company shall pay to the Anglo Company 2,000fr. (£80) per day from the 31st December, 1886, until the date of the service of the judgment.

The amount of damages thus awarded to the Anglo-American Company is about £32,000.

MEETINGS OF SCIENTIFIC SOCIETIES.

(Week ending Thursday, 19th January.)

TO-DAY (FRIDAY), January 13th.

ASTRONOMICAL SOCIETY.

8 p.m. Meeting.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Supplemental Meeting for Students. Paper to be read— "Railway Engineering in British North America." By Mr. ROBERT J. MONEY, Stud. Inst. C.E.

TUESDAY, January 17th.

ROYAL INSTITUTION.

3 p.m. The first of ten Lectures on "Before and After Darwin." By Mr. GEO. J. ROMANES, M.A., &c.

SOCIETY OF ARTS.

8 p.m. Meeting of Foreign and Colonial Section. Paper, "The Colonies and Dependencies of the Netherlands and of Portugal." By Mr. A. J. R. TRENDELL, C.M.G.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be further discussed, "The Use and Testing of Open-Hearth Steel for Boiler Making." By the late HAMILTON GOODALL, A.M.I.C.E. Paper to be read (time permitting), "The Erection of the 'Jubilee' Bridge over the River Hooghly, on the line of the East Indian Railway." By Sir BRADFORD LESLIE, K.C.I.E., M.I.C.E.

WEDNESDAY, January 18th.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. Paper, "Methods of Taking Ballot." Three Papers by Messrs. JOHN LEIGHTON, JAMES WITHERS and JOHN IMRAY. The ATTORNEY-GENERAL, M.P., will preside.

ROYAL METEOROLOGICAL SOCIETY.

7 p.m. Ordinary Meeting. Paper on "The Non-Instrumental Meteorology of England, Wales and Ireland, 1878-1885." By G. M. WHIPPLE, B.Sc., F.R.Met.Soc., F.R.A.S.

8 p.m. Annual General Meeting. The Report of the Council will be read, the Election of Officers and Council for the ensuing year will take place, and the President, Mr. W. ELLIS, F.R.A.S., will deliver his Address.

THURSDAY, January 19th.

CHEMICAL SOCIETY.

8 p.m. Meeting.

THE ROYAL SOCIETY.

4:30 p.m. Ordinary Meeting.

ROYAL INSTITUTION.

3 p.m. Lecture on "The Walker School." By Mr. HUBERT HERKOMER, M.A., A.R.A.

"The Electrician" in America.

"THE ELECTRICIAN" *can be obtained in America from* D. VAN NOSTRAND, *23, Murray-street, and 27, Warren-street, New York.*

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

THE PROPRIETORS *of* "THE ELECTRICIAN" *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

THE ELECTRICIANS' DIRECTORY.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY IS NOW READY.

NOW READY.

Volume XIX. of "The Electrician," strongly bound in cloth, is NOW READY, price Ten Shillings and Sixpence.

Cases for binding "The Electrician," price Two Shillings, Now Ready.

1887.

The Telephone.

THE UNITED TELEPHONE COMPANY.—This company, which is well known as the parent of many of the provincial companies, is essentially a metropolitan institution, and with the exception of its connection with Brighton has no trunk lines attached to its system. Down to the end of September last its subscribers in London numbered 4,596.

THE NATIONAL TELEPHONE COMPANY.—This large and important telephone company carries on business not only in Yorkshire, which is its head-quarters, but in Scotland as far as Inverness, as well as in the districts in England of which Whitehaven, Paisley, Wolverhampton, Hanley, Nottingham, and Birmingham are the centres; and in Ireland by the single town of Belfast. The total number of lines erected by this company down to the end of the year amounted to 8,478, made up of 7,301 exchange lines, and 1,177 private lines. 104 Exchanges are actually in operation, connected with which and through them to the trunk lines are 192 call offices. These trunk lines are connected largely with the Lancashire and Cheshire Exchange systems; and the town of Birmingham is about to be connected by trunk wires to the United system in London. Some idea may be formed of the progress made in the principal districts served by this company during the past year by the following figures:—The Glasgow district has now 1,537 exchange and 267 private wires, against 1,266 and 255 in 1886. In Edinburgh and Leith the exchange lines have increased from 367 to 407; and in Aberdeen from 493 to 527. The Leeds district has two additional Exchanges, the lines being increased from 436 to 544; and the private lines from 79 to 94. For Birmingham and its suburbs the exchange lines now number 538, their total in 1886 being only 475. The tariff is generally £10 per annum; but in the larger towns it is £15.

THE LANCASHIRE AND CHESHIRE COMPANY.—This important Telephone Exchange Company, whose head office is in Faulkner-street, Manchester, has now in active operation what may be described as three great circles of communication, the centres of which are respectively Manchester, Liverpool, and

Digitized by Google

Blackburn. A similar district, embracing North Wales, and of which Wrexham will be the chief centre, is in process of formation, and it is intended ultimately to connect this with the trunk systems of the other districts. In the three Lancashire and Cheshire districts there are at present 35 towns in which Exchanges are fitted up; and of these no fewer than 29 are in trunk wire communication, not only with each other, but with some of the principal manufacturing towns of Yorkshire, including Leeds, Bradford, Halifax, Huddersfield, Wakefield, &c. The rates charged under these systems are in most cases £12 per annum; but in Manchester, Liverpool, and Birkenhead the charge is £20. These rates are for subscribers situated within a mile of the local centre, an additional charge of £7 per mile being made for distances beyond the first mile. For an extra annual charge of £12 subscribers to the Manchester and Liverpool city systems may have their residences connected; and at a proportionately lower rate the same privileges are extended to the smaller towns. Some idea of the extent to which these systems are being patronised may be gathered from the following figures:— In Manchester and Salford there are 1,706 subscribers—1,291 to the Exchange, and 415 private connections. To this may be added the public call offices, which now number 31. In Liverpool, not including Birkenhead, the figures are respectively 1,405, 500, and 25 call stations. In Blackburn there are 233 Exchange, and 38 private subscribers, and Preston numbers nearly as many. Most of the towns have two or three public call stations; Blackpool has 6, Southport 4, and Birkenhead 5. The grand total of subscribers at Christmas of the year just ended for the whole system covered by the Lancashire and Cheshire Company was 5,309, made up of 3,934 to the Exchanges and 1,375 for private lines. The call offices numbered 122. The income derived from the trunk wire and call office systems alone amounted last year to £7,500. The company's gross annual income is over £90,000. On 30th June last the company owned 7,250 miles of wire, about one-third of which is employed for intercommunication between towns. Fully 50 per cent. of the subscribers make regular use of the trunk wires, the number of calls reaching 3,000 per day, those for the purely local systems being 25,000.

Western Counties and South Wales Company.—From Bristol as a centre, the operations of this company extend to Cardiff, Hereford, Shrewsbury, and Malvern in one direction, and to Exeter, Torquay, and Plymouth in the other; while among the southern counties the towns of Bournemouth, Portsmouth, Southampton, and even Jersey are provided for. A comparison of the returns furnished for the two last years shows that the number of subscribers has increased from 1,318 at the end of 1886 to 1,995 in the first week of December, 1887. This last-mentioned total is made up of 1,536 subscribers to Exchanges, and 459 private line renters. The major part of the increase is due to extensions into fresh districts, or the rapid rise of business in towns where the service had been only recently installed in 1887. Bristol counts 489 customers and Plymouth 261. It should be remembered that this company, which is a subsidiary of the United, has been in existence only three years. A notable fact revealed in these returns is the amount of telephone business done in what may be called residential towns as distinguished from commercial. In Bournemouth and Torquay, for example, there are 170 and 131 subscribers respectively to the Exchanges; while in Cardiff there are only 68; and in Portsmouth and Swansea 132 and 134. Most of the service is day and night, at all events for all the business towns and for the holiday resorts, such as Torquay and Bournemouth. The rate for annual subscribers to the Exchange at Bristol and Clifton is £15, with some reduction if the agreement is for a term of years; but for all other places £12 is the usual charge. For an extra charge of £5 the subscriber can be connected to his private residence if within a quarter of a mile, a small extra covering distances beyond this when a term of 4 or 7 years is guaranteed. Although this company has been established but a comparatively short time it has already erected trunk lines which now exceed 900 miles. Bristol is connected with Bath, Gloucester, Newport, Cardiff, and Swansea; and Cardiff in turn is in connection telephonically with Aberdare, Merthyr, &c. Besides the places just mentioned Swansea speaks to Briton Ferry, Llanelly, and Landore; while Bournemouth and Poole, Torquay and Newton Abbot have trunk lines of their own united with the general system. The charges for using these long-distance lines are 6d., 9d., and 1s., according to distance, the conversation lasting three minutes. From Swansea to Bristol it is 1s., from Bristol to Bath it is only 6d. The company contemplate the erection of a trunk line to London, with which the whole of its system will then be in connection through its Exchanges. The gross rental for the year just ended is estimated at £20,000, of which sum £3,500 or more is payable to the Post Office and the "United," of which this company is a subsidiary, for royalties.

The South of England Company.—This company furnishes us with information only with respect to the towns of Eastbourne, Hastings, and St. Leonards. In the first-named place there are 70 Exchange and 23 private subscribers. At Hastings and St. Leonards they have 80 on the Exchange and 24 private connections. The tariff is exceptionally low—only £10 per annum. According to the *Bulletin International d'Electricité* the South of England Company embraces Great Yarmouth and its neighbourhood, as well as Oxford, Margate, and Maidstone, in its operations, and numbered last April 1,130 subscribers, trunk lines connecting Folkestone and Dover, Yarmouth and Norwich, Maidstone and Chatham, and Brighton and London.

The Northern District Company.—This company, whose centre of operations is at Sunderland, now possesses 576 Exchange wires, and lets 123 private wires. Of the Exchanges 13 are connected with trunk lines, of which the company has erected 1,144 miles, the Exchanges covering an additional 475 miles, and the private wires 295. The number of daily calls have increased from 1,437 in 1886 to 2,650 in 1887. It is intended to link this district to the National Company's system in Yorkshire, and thence to the Lancashire and Cheshire district.

The Sheffield Telephone Exchange.—This Exchange was inaugurated by private enterprise early in 1879, and as a private undertaking it has since been continued, enjoying a progressive and prosperous career. As a telephone exchange it is noteworthy on account of its independent and unique position in not being attached to, or subject to, any of the larger telephone companies, but working immediately under the license of the Postmaster-General. As Sheffield is situated in the very heart of the National Telephone district, it is not surprising that efforts have been made to bring about an amalgamation or working agreement between the two systems; but at present these efforts are not meeting with any encouragement on the side of the Sheffield Telephone Exchange, which apparently desires to maintain its complete independence. The Sheffield Exchange has more than 400 subscribers, as well as 120 private wires, and additional wires are continually being erected. Thirteen call offices are open to the general public on payment of a small fee. The adjacent town

Digitized by Google

of Rotherham has for several years been in direct connection with the Sheffield Exchange, but a local Exchange has now been opened in Rotherham, which gives communication between the towns by means of trunk wires. The system is also being extended so as to reach Swinton, Mexbro', Wath, Wombwell, and Barnsley, thus uniting the whole of the South Yorkshire coalfields. There is a total length of 600 miles of wire on poles, and much of this passes through a heavy, acid-charged atmosphere. The rapid multiplication of the wires in the town and electrical considerations have rendered it necessary to employ copper wire, which besides being better adapted for telephonic transmission will also probably withstand the destructive effects of the Sheffield atmosphere. The operations of the proprietary have not been confined to Sheffield and the neighbourhood only. Private Telephone Exchanges have been erected for Her Majesty the Queen at Windsor, Balmoral and Osborne; for H.R.H. the Prince of Wales at Sandringham; for the Dukes of Norfolk, Devonshire and Newcastle, and for many other establishments in all parts of the country.

THE NEW TELEPHONE COMPANY.—This company, which was formed to work the patented valve telephone of Prof. S. P. THOMPSON, having established its right to an independent existence, is now actively pushing business by methods differing materially from those of the older companies. The New Telephone Company sells its instruments outright, as well as the wires, batteries, and materials necessary for maintaining them. Outside the field of the Exchanges which we have been describing there is undoubtedly room for installations of a private or local character, and it need not surprise us to learn that many large establishments, such as asylums, ironworks, collieries, and even railways have adopted the proprietary system devised by this company, whose instruments are said to be giving satisfaction wherever they are adopted.

THE TELEPHONE COMPANY OF IRELAND.—We have no later information relating to this company than the beginning of last year, when the number of subscribers in Dublin and Dundalk amounted to 915.

EUROPEAN SYSTEMS.—Of the general extension of the telephone system in Europe during the three years ended 1886 the following statistics have lately been compiled, and may here be interesting in connection with our survey of the progress of British telephony in 1887. No similar statistics are yet available relating to the American continent. The increase in the number of telephone wires was greatest in Switzerland, where it was 1,700 per cent. (from 2 in 1883 to 36 in 1886); Germany 333 per cent. (from 21 to 91); Austria, 267 per cent. (from 3 to 11); Russia, 233 per cent. (from 6 to 20); and Sweden, 200 per cent. (from 5 to 15). Belgium and Holland follow a long way behind, with an increase of only 50 per cent. (from 10 to 15). In Italy the number of telephone lines increased but 23 per cent. (from 13 to 16); in Great Britain 19 per cent. (from 75 to 89); and in France 11 per cent. (from 18 to 20). Germany had at the close of 1886 the largest number of telephone lines, 91; and Austria the smallest, 11. The increase in subscribers has been in proportion to the growth in the number of lines. Switzerland here also heads the list, subscribers having increased by 486 per cent. (from 835 in 1883 to 4,900 in 1886). In Germany the increase was 308 per cent. (from 3,613 to 14,733); Russia, 291 per cent. (from 1,451 to 5,280); Sweden, 267 per cent. (from 1,553 to 5,705); Austria, 248 per cent. (from 870 to 3,032); Belgium and Holland, 151 per cent. (from 2,331 to 5,858); and Great Britain, 107 per cent. (from 7,287 to 5,114). France and Italy are at the bottom of the list, the increase in the number of subscribers in the former country having been only 62 per cent. (from 4,437 to 7,175), and in the latter 52 per cent. (from 5,507 to 8,346). Great Britain still had the largest number of telephone users, 15,114; Austria the smallest, 3,032.

1887 IN AMERICA.

(FROM OUR AMERICAN CORRESPONDENT.)

While the advance made in electricity here during the year just closed has been eminently practical and commercial, there may still be chronicled progress in the various branches which involve theoretical application. Looking over the field we find first in the telegraph an addition to Edison's phonoplex of a year ago, by means of which he is enabled to convert a single line into a triplex, by means of two diaphragm receivers added to the regular Morse receiving apparatus. In his first apparatus but one diaphragm receiver was employed, which was made to operate by transmitting a momentary induction current over the wire, which snapped a telephone diaphragm, and which did not interfere with the Morse transmission. The additional diaphragm now employed is acted upon by a rapidly vibrating current, which is also read off in the usual way, the dots and dashes being recognised by the short and long buzzes.

This year also has seen the first line regularly equipped with the train telegraph apparatus, by which constant communication can be had between a moving train and the station. The system is employed on the Lehigh Valley Railroad, and it differs from that used by Phelps in 1885 in that static induction is employed instead of dynamic, the roof of the train being charged from the wire running alongside the track. I might also draw attention to the system devised by Absterdam, in which signals are re-transmitted automatically from the distant end of the line, so that all manual labour for the verification of messages is unnecessary.

In the field of telephony I would call attention to the "make and break" transmitter of Field. Heretofore, "make and break" transmitters have depended upon the action of the voice to perform the "make and break"; but in the Field and Eickemeyer transmitter the break is performed automatically, and, in fact, the transmitter is under constant vibration, the voice merely bridging parts of these "makes and breaks," affecting the current in the external circuit in correspondence with the vibration of the voice. Another telephone also brought out consists of a number of reeds placed in proximity to the magnet, the idea being that the articulations of the voice would be better recorded by employing receiving apparatus having a number of differently tuned vibratory receivers.

In the field of phonographs we find Edison at work on his old idea, but he has now come to the use of a cylinder of wax, upon which a graving tool cuts a line corresponding with the vibration of the voice. Bell and Painter have also worked on a similar line during the year. Berliner has brought out a phonograph, or "gramophone," in which he employs the old Leon Scott principle, by tracing a line on a flat disc covered with lampblack, and then employing this as a negative to produce a photo-engraving, which then serves as a guide or matrix to the stylus attached to the reproducing diaphragm. Of the electric speech recorders, we have that produced by Hunter, who acts upon carbon paper by means of a stylus attached to a diaphragm, compressing it in accordance with the vibrations of the voice, and then employs this carbon sheet for reproduction by including it in a circuit, which is varied by the vibrations in the resistance produced by the indentations first made.

In Irish's phonograph an incandescent stylus burns a line in a strip of paper, the depth of which corresponds to that of the articulations of the voice, and by then including this strip of paper in a circuit and feeding carbon to the strip, the resistance will be varied in correspondence with the depth of indentations of the strip.

Digitized by Google

In electric lighting the various induction systems may be said to have almost monopolised attention in this country, though the continuous current has by no means been forgotten. The Westinghouse system has been further developed this year, and, in addition several new systems have been produced. Among these we note the ingenious application of Diehl, in which a continuous current is employed to send a pulsating one through two branch circuits, and thus by induction producing effects in the secondary circuits of incandescent lamps specially constructed for the purpose. After passing the two branches, the current becomes a continuous one, and may be employed for arc lighting and similar purposes. Pfankuche has also brought out an induction system in which he employs a continuous-current machine, the direction of the current being reversed.

During the year Elihu Thomson has brought out a very ingenious method of regulating three-wire systems by placing a motor dynamo in connection with the circuit, each commutator being connected to the other sides of the system. When the potentials of both sides are alike, the action of the two windings will neutralise each other; but, if one rises in excess of the potential of the other, that winding is converted into a motor which will drive the other winding as a dynamo, returning to the defective circuit the current which the other has in excess, and thus keeping the balance.

Eichemeyer has also brought out during the year an ironclad dynamo, in which the field coils are wound directly over the armature, the whole being enclosed in an iron envelope.

In the motor and electric railway branch America has seen wonderful developments this year. I need not enter into the number of new roads equipped or into the number of stationary motors that have been used during the year, as your columns have already chronicled those facts, but I may draw attention to a few novelties in this direction. Field has devised a system in which the tops of the conduits serve as rails, and within which is an insulated conductor. The conductor in one conduit is connected to the positive pole of the dynamo, the negative pole of which is connected to the ground; while in the other conduit the conductor is connected to the negative terminal of a dynamo situated at the other end of the line, with its positive terminal groundless. This keeps the resistance of the line constant, no matter where the car may be situated, and allows of working with two potentials, and in case of a breakdown of a machine at one end of the line, the other still keeps the road in operation. Irish has recently brought out a system in which the conductor is laid in a flexible conduit, the car passing over compressing the conduit, and making contact with the conductor within, but immediately releasing the contact when it has passed that point.

You have kept well up in the work that has been done in thermo-electricity during the year, and I only need mention by name, therefore, the Edison pyromagnetic motor, and the electric furnace generator of Berliner, and elsewhere I give the latest developments of Acheson. This brings me to the subject of batteries. There is very little to be reported in this, but I may foreshadow the early appearance of a form of cell which is claimed to remove all the difficulties which stand in the way of successful commercial lighting by primary batteries, so that not only in England but here is the question of lighting by primary batteries a live one.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(*Concluded from page 187.*)

Persulphate of Iron and Sulphate of Potassa.—A weak solution of the persulphate was first obtained, to which was added a solution of sulphate of potash. With the current from four Daniell cells and large anode surface, a bright deposit of iron of a steel grey colour was obtained upon a brass plate soon after immersion. The deposition was rather slow at first, until the anode surface was increased, and there was a good deal of hydrogen given off. After the plate had been in the bath about half an hour, a good coating of iron was obtained on both sides of the plate, and small crystals of metallic iron were found attached to one corner of the plate, showing that the deposition had really proceeded with some rapidity during the time.

Persulphate of Iron and Sulphate of Ammonium.—It was next determined to ascertain if the addition of sulphate of ammonia to a solution of the persulphate of iron would favour the deposition of the metal. For this purpose a dilute solution of the persalt was taken, and to this was added a small quantity of sulphate of ammonia, which was dissolved, with stirring, in the liquid. On immersing a brass plate in this bath—the current from three Daniells being used—it at once become coated with a film of iron of a darkish colour, the upper portion of which was of a blue tint. The current being evidently too strong, a single cell was next tried, when a prompt deposit of iron of a dark grey was received upon a fresh plate. The solution was now diluted with water, and a new plate immersed, when the deposition took place more gradually, and indeed too slowly. Two more cells were now added, when the film upon a fresh plate was at first of a blue colour, but after a few moments it became tolerably white, and was perfectly reguline and adherent, the deposit having taken place on both sides of the plate, proving that the solution was a fairly good conductor. I may say that this result somewhat surprised me, for although I had succeeded in obtaining metallic deposits from iron persalts from various solutions, *as a matter of fact*, I never expected that a tolerably good depositing solution could be formed from such salts; but this, so far as I have gone with this latter experiment, really appears to be the case.

Persulphate of Iron and Sulphate of Soda.—A solution was formed by adding to a rather weak neutral solution of persulphate of iron, powdered sulphate of soda crystals, a little at a time, and stirring the liquid until this salt was dissolved. With the current from three Daniells, a deposit of iron at once commenced to form on the corners of a brass cathode, the film gradually increasing until the whole of the immersed surface—about two square inches—was covered. The deposit, which was of a blue-grey colour, was very streaky and irregular; to remedy this, if possible, the bath was further weakened by addition of water, which somewhat improved the character of the film; but this, however, still remained patchy or mottled. The bath was again diluted, at which point it was exceedingly weak, but still yielded a prompt coating of iron upon a clean brass plate. To obtain a uniform coating, and to improve the colour of the film if possible, the plate was now gently moved about in the bath—a large anode surface being exposed—when the metal deposited in a more uniform condition and of a good white colour. The results thus obtained further indicate the direction in which we must steer if we wish to obtain metallic deposits of iron from solutions of its persalts, with or without the admixture of other substances, namely, in the direction of the pump. Extreme dilution of the electrolyte appears to be an absolutely necessary condition. Although solutions of the persalts of iron have no practical significance so far as relates to the deposition of the metal upon other metallic surfaces for the purposes of art, I was desirous, in these latter experiments, to ascertain, *first*, if iron could be deposited at all from any or all of these solutions; and, *second*, under what conditions. In my first experiments with the persalts I was, in common with others, unsuccessful, and it was not until I had obtained an actual film of reguline metal from a pernitrate solution, that I became convinced of the possibility of reducing the metal from persalts provided the proper conditions could be arrived at. Those conditions I discovered after a very extensive and tedious course of experiments, and if I were to go over the same ground again I should exactly reverse the basis on which they were conducted; for, instead of commencing with a moderately-strong solution of any given persalt, and gradually reducing its strength, as occasion required, by additions of water, I should start with a measured quantity of water, and to this would add, by small quantities at a time, a concentrated solution of

Digitized by Google

the salt under trial, these additions being made until a film of iron appeared upon a clean brass or copper cathode.

Perphosphate of Iron.—Hydrated peroxide of iron was digested in a boiling solution of phosphoric acid, and the solution afterwards filtered and diluted with water. With a current from three Daniells a blue film of iron was first obtained upon a brass plate, but after a few minutes' immersion the deposited metal acquired the characteristic colour of iron, though not so white as that obtained from a solution of the protosalt.

Lactate of Iron.—A solution of this salt was first prepared by digesting a quantity of fine iron wire in a strong solution of lactic acid for many hours, when a pale green solution resulted, which, after moderate dilution, was electrolysed with the current from three Daniells in series. There was a brisk liberation of hydrogen, and after a few minutes' immersion of a brass cathode a film of iron of a somewhat dark colour appeared upon its surface. No deposit could be obtained with a smaller number of cells than those mentioned. A solution of lactate of iron was also prepared by dissolving carbonate of iron in a strong and warm solution of lactic acid, and the liquid was used in its warm condition with the same number of cells, when a prompt film of iron was obtained upon a brass plate, but the colour, as before, was of a dark colour.

Perlactate of Iron.—A strong solution of lactic acid was first heated, and moist hydrated peroxide of iron then introduced in small quantities at a time, and the heat kept up until the acid was neutralised. The vessel was then set aside until cool, and the clear liquor, which was of a deep orange colour, was afterwards decanted for use. With the current from three Daniells in series, a dark coloured and somewhat iridescent film of iron slowly formed upon a brass cathode, and this was found to be firmly adherent. The solution was then gently heated, and tried with the same current, when the deposit was somewhat more prompt, and the colour of the film improved, especially when the plate was slowly moved about in the bath.

In pursuing the experiments described in this and the preceding papers, my aim was to obtain deposits of metallic iron, if possible, from even the most refractory iron salts, and in this, I am pleased to say, I generally succeeded, by making such modifications of current strength and density of the electrolytes operated upon, as from time to time occurred to me. In arriving at more or less satisfactory results with solutions that presented much difficulty, I frequently had to make a very considerable number of trials before I succeeded in finding out the conditions necessary to obtain the desired film of iron of a proper reguline character. When these conditions were approached, further investigation was often necessary to ascertain whether further modifications would give still better results; and it was not until such additional trials had been made that I felt satisfied with the final result of my labour. From a practical point of view, I am fully aware that many of the experiments I have recorded will have but little interest. To the student of electro-metallurgy, however, the behaviour of various solutions of metallic salts under electrolysis cannot fail to possess at least the interest which always attaches to fact. Indeed, when we consider the comparatively meagre information which has been furnished us by the various investigators of electro-chemical phenomena, concerning the electrolysis of metallic solutions other than those which have a more or less practical application in the arts, it would appear that further investigation should be made in this direction, and to this agreeable task I have for some time past—and purpose continuing to do so—devoted myself, believing that not only the student, but the practical electro-metallurgist, may derive some beneficial knowledge from the records of electrolytic experiments with a considerable number of metallic solutions.

If we consider the practical application of iron solutions in the electro-deposition of that metal upon other metallic surfaces, as in the so-called steel-facing of engraved copper plates, for example, I am disposed to give the preference to the following salts for making up iron baths, and if these are prepared with care, and from good materials, there should be no difficulty in obtaining good results from either of them. 1. The ammonio-sulphate of iron. 2. Sulphates of iron and magnesia. 3. Sulphate of iron and chloride of ammonium. 4. Sulphate of iron *per se*. To prevent the solutions from becoming oxidised many different substances have been added to iron baths, as glucose (grape sugar), glycerine, &c., but I am disposed to think, from experiments I made in this direction, that small doses of citric or tartaric acid will be found more effectual, while these vegetable acids have also a tendency to improve the brightness of the iron deposit. Again, in making up iron baths for the practical deposition of the metal, it is often recommended to employ an anode of large surface—that is, considerably larger than that of the article to be coated. I am disposed to suggest, however, that the strength of the solution and density of current should be so regulated that the metal will be deposited freely and uniformly with an anode surface about equal to or, at least, not greatly exceeding that of the cathode. My object in suggesting this is that I have found the metal to deposit well under such conditions from the solutions named, and such being the case, there can be no real advantage in greatly exceeding the limit of anode surface. A solution will, I believe, yield more uniform results and maintain its normal condition for a longer period if a uniform density of current be always maintained, and the liquid kept in such a condition that the iron will freely deposit when the electrodes are of about equal surface. To my mind it is generally a sign that the electrolyte is defective, or the current too weak, when a large anode surface is necessary to obtain a metallic deposit of good quality, and at a proper rate of speed to render the film adherent. In depositing iron from any of its neutral solutions great care should be taken, when lifting the article out of the bath to ascertain how the deposit is progressing, that the film be not exposed to the action of the air for any length of time, since the exposure of a few seconds only would be quite sufficient to form a film of oxide upon the surface, which would effectually prevent the subsequent layer of metal from adhering to the first. We all know, as I pointed out many years since, that metals do not adhere well to their kind when deposited by electrolysis; thus, gold does not firmly adhere to gold, silver to silver, and so on; but this is more remarkably the case in respect of nickel, which I believe cannot be made to adhere to the same metal by any electrolytic method whatever. I have been prompted to make the above observations in the hope that they may in some degree assist in guiding those whose inclination or duties may lead them to engage in the electro-deposition of iron upon other metals.

PORTABLE VOLTMETERS FOR MEASURING ALTERNATING POTENTIAL DIFFERENCES.*

BY W. E. AYRTON AND JOHN PERRY.

(*Continued from page 209.*)

The action of these instruments is quite easy to understand; but the mathematical calculation of the way in which the deflection of the pointer for a given potential difference is varied by varying the dimensions of the magnifying spring, the initial sag given to the wire, and the dimensions of the wire, is not quite so easy to work out. We have, however, succeeded in reducing the solution to a comparatively simple form, and the following comprises the consideration of—

A. The general formulæ and the law of graduation.
B. Waste of power in the voltmeter.
C. The range in volts of the voltmeter.
D. The greatest angular deflection of the pointer.
E. Uniformity of the scale divisions.
F. Correction for temperature.

A.—General Formulæ and Law of Graduation.

Let A O B (Fig. 10) be one of our fine wires or two opposite spokes of our bicycle-wheel form of voltmeter, the size of the hub being neglected. Let

$$AO = OB = \tfrac{1}{2} l, \quad OQ = y.$$

* Paper read before the Society of Telegraph-Engineers and Electricians on December 25, 1887.

Digitized by Google

Let the diameter of the wire be d, and the specific resistance of its material be ρ when its temperature is θ degrees above the temperature of the surrounding metal case: then, if the case does not alter greatly in temperature,

$$\rho = \rho_0 (1 + k\,\theta). \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where k is the coefficient of increase of resistance per degree centigrade, and ρ_0 is the specific resistance of the material when θ is nought.

When $\theta = 0$,
let $l = l_0$,
and $y = y_0$;
then $l = l_0 (1 + a\,\theta)$,

where a is the coefficient of increase of length per degree centigrade.

$$y^2 + A\,Q^2 = \tfrac{1}{4}\,l^2,$$
$$y_0^2 + A\,Q^2 = \tfrac{1}{4}\,l_0^2;$$
$$\therefore\ y^2 - y_0^2 = \tfrac{1}{2}\,l_0^2\,a\,\theta, \text{ approximately} \quad . \quad . \quad (2)$$

since a is small.

In that very useful treatise of Dr. Everett's, "Units and Physical Constants," there are given the results of Mr. McFarlane's and of Professor Tait's experiments on the rate of loss of heat in air at ordinary pressure from copper for various differences of temperature between the copper and the surrounding space, but no indication is given as to the form of the radiating body, nor of its size, and hence people have used Mr. McFarlane's results as if they applied to bodies of any shape and size, and so have been led in some cases to erroneous conclusions. As a matter of fact, Mr. McFarlane's values for the rate of loss of heat by radiation and convection given in Dr. Everett's "Units and Physical Constants" *apply only to a copper ball of 2 centimetres radius*, since this, we find, was the cooling body employed by Mr. McFarlane in the experiments in question, as mentioned in Mr. McFarlane's paper communicated by Sir W. Thomson to the Royal Society in 1870.

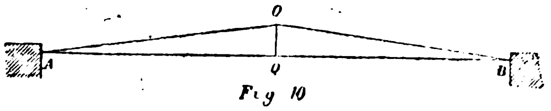

Fig 10

But in a very valuable book published two years previously to that—viz., in 1868—by Mr. Box, and called a "Practical Treatise on Heat," there is a table given on page 151 (which has been much used by engineers) showing the loss of heat from contact with air with horizontal cylinders and spheres. It was deduced, we rather think, from M. Peclet's experiments, and it shows clearly that the loss of heat per unit area increases as the diameter of the cylinder or sphere diminishes. Mr. Box used the Fahrenheit scale for temperature, a square foot as his unit of area, a pound for his unit of mass, and an hour for his unit of time; but, reducing his formulæ to the C.G.S. system, we find that the loss of heat (gramme, C. deg.) per second, per square centimetre of surface, per 1 deg. C. excess, is

$$0{\cdot}00005710 + \frac{0{\cdot}0001057}{a} \text{ for a long } \textit{horizontal} \text{ cylinder.}$$

$$\text{and } 0{\cdot}00004928 + \frac{0{\cdot}0003609}{a} \text{ for a sphere,}$$

a being in the former the radius of the cylinder in centimetres, and in the latter the radius of the sphere.

Applying Box's formula for a sphere to the case where a is 2 centimetres, the radius of Mr. McFarlane's ball, we obtain for the loss of heat (gramme, C.deg.) per second, per square centimetre of surface, per 1deg. C. excess, the number 0·0002297—a number which is between Mr. McFarlane's value for polished copper (0·000178) and for blackened copper (0·000252). There is, therefore, every reason for believing that Box's formula is at any rate approximately correct.

Let us take as a first approximation that the rate of loss of heat is directly proportional to the difference of temperature. This we know is not strictly true, and the error arising from the assumption will be furthered considered under section B—"Waste of Power in the Voltmeter." Then, if $\epsilon\,\theta$ be the heat-power *in watts* given out per square centimetre of surface of the wire when the excess of temperature is $\theta°$ C.,

$$\epsilon = \frac{0{\cdot}00005710 + \dfrac{0{\cdot}0001057}{a}}{0{\cdot}239}.$$

Now the resistance of the wires is $\dfrac{4\,l_0\,\rho}{\pi\,d^2}$; so that, if V volts be the potential difference at its terminals, $\dfrac{V^2\,\pi\,d^2}{4\,l_0\,\rho}$ watts are developed in the wire, and $l_0\,\pi\,d\,\epsilon\,\theta$ = heat-power emitted in watts; so that

$$l_0\,\pi\,d\,\epsilon\,\theta = \frac{V^2\,\pi\,d^2}{4\,l_0\,\rho} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

or

$$\theta = \frac{V^2\,d}{4\,l_0^2\,\epsilon\,\rho} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

If the thickness of the wire be very small, and if Box's formula continue to hold for very thin cylinders,

$$\epsilon = \frac{0{\cdot}0001057}{0{\cdot}239\,a}, \text{ approximately};$$

$$= \frac{0{\cdot}0008848}{d}, \quad \text{"}$$

hence

$$\theta = \frac{V^2\,d^2}{0{\cdot}003539\,l_0^2\,\rho} \quad \text{"}$$

so that to raise a fine wire of a given length, made of a given material, to a given temperature above that of the case of the instrument requires that the potential difference maintained at the ends of the wire shall be inversely proportional to the diameter of the wire, approximately.

If C be the current in amperes flowing through the wire,

$$C = \pi\,d^{\frac{3}{2}}\sqrt{\frac{\epsilon\,\theta}{4\,\rho}}.$$

Substituting the value just obtained for ϵ for very fine wires, we have

$$C = 0{\cdot}01487\,\pi\,d\sqrt{\frac{\theta}{\rho}}, \text{ approximately};$$

or the current required to maintain a fine wire of a given material at a definite excess of temperature is approximately directly proportional simply to the thickness of the wire.

This result was obtained experimentally by Professor Forbes in 1884,* but he appeared to regard it as a result that would not have been expected from experiments previously made on much thicker wires. Mr. Preece also published results,† in the same year, of experiments made on fine wires, and he also speaks of the results of experiments "contradicting" the law which he obtains theoretically. Whereas it appears to us that the current having to vary directly as the diameter, and not as the diameter raised to the power three halves, in order that *very fine* wires may be maintained at the same temperature, is in entire conformity with the true law of the loss of heat by radiation and convection, which was published certainly as early as twenty years ago by Mr. Box.

Equation (5) becomes

$$\theta = \frac{V^2\,d}{4\,l_0^2\,\epsilon\,\rho_0\,(1 + k\,\theta)},$$

or

$$\theta = \frac{V^2\,d}{4\,l_0^2\,\epsilon\,\rho_0\left(1 + k\,\dfrac{V^2\,d}{4\,l_0^2\,\epsilon\,\rho_0}\right)}, \text{ approximately} \quad . \quad (5)$$

One law of the magnifying spring is that

$$\phi = \frac{s}{r}\,(y - y_0) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where ϕ is the rotation of the pointer in radians, s is a number depending upon the material of which the spring is made, and has a value about 1 radian for phosphor bronze, and r is the radius of the spring.‡

Digitized by Google

Substituting for y from (6) in (2), we have, as

$$y = \frac{r\phi}{s} + y_0,$$

$$\frac{r^2}{s^2}\phi^2 + 2\frac{r}{s}\,y_0\,\phi = \tfrac{1}{2}\,l_0^2\,a\,\frac{V^2 d}{4\,l_0^2\,\epsilon\,\rho_0\left(1 + k\dfrac{V^2 d}{4\,l_0^2\,\epsilon\,\rho_0}\right)},$$

$$\text{or}\quad \phi^2 + 2\,\frac{s}{r}\,y_0\,\phi = \frac{s^2}{r^2}\,\frac{d\,a}{8\,\epsilon\,\rho_0}\,\frac{V^2}{1 + \dfrac{k\,d}{4\,l^2\,\epsilon\,\rho_0}V^2} \quad . \; . \; . \; . \; . \; . \quad (7)$$

or, if $A = \dfrac{s^2}{r^2}\,\dfrac{d\,a}{8\,\epsilon\,\rho_0}$, and $B = \dfrac{k\,d}{4\,l_0^2\,\epsilon\,\rho_0}$,

and if $\dfrac{s}{r}\,y_0$ be called ϕ_0, then

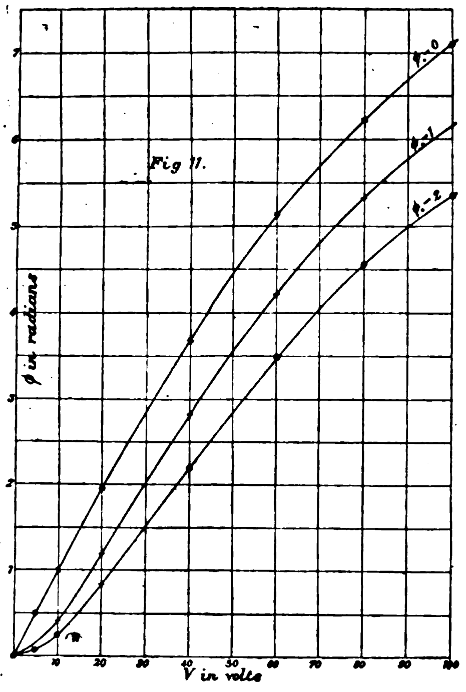
$$\phi^2 + 2\,\phi_0\,\phi = \frac{A\,V^2}{1 + B\,V^2} \quad . \; . \; . \; . \; . \; . \quad (8)$$

and hence

$$\phi = \phi_0\left\{-1 + \sqrt{1 + \frac{A}{\phi_0^2}\,\frac{V^2}{1 + B\,V^2}}\right\} \quad . \; . \; . \quad (9)$$

There are discrepancies in this result, due to—

1st. Our assuming (1). But it will be found that the error due to this assumption is not large for the usual temperatures of the instrument when platinum-silver wire is employed. See F—"Correction for Temperature."



2nd. Our assuming ϵ to be independent of θ. If ϵ is not constant, the law (9) alters in shape. As we never use (9) for the purpose of graduating, but merely to give us some approximate knowledge of a general law, this will not affect in any way the accuracy of the instrument.

3rd. We have not taken into account the fact that time is needed to attain the state of equilibrium indicated by (4), so that θ might be expected to rise higher on first starting the current than its true steady value; but we find experimentally that this time is quite inappreciable with a *very fine* wire placed *horizontally*.

4th. Our having neglected small changes in y due to the tensile strain in the wire. It can be proved that these are unimportant, except when y_0 is smaller than we are ever able to have it in our instruments.

5th. Our having dealt with certain small quantities as if they were indefinitely small.

B is found to be small in our instruments, and when y_0 is very small it is obvious that the deflection ϕ of the pointer is very nearly proportional to V, the potential difference. When y_0 is not small, the readings increase at first in proportion to the square of the volts, and then become more nearly proportional to the volts. In fact, the divisions for volts of the scale of the instrument get rapidly greater for small readings; then, as the readings become higher, the divisions become equal to one another; and, if the range is high enough, they become somewhat smaller again, due to the change of resistance with temperature making its effects felt.

For the sake of illustration we have drawn the three curves shown in Fig. 11, taking

$$A = \cdot 01$$

and $$B = \cdot 0001,$$

and the values 0, 1, and 2 for ϕ_0.

If such a spring is used that $\dfrac{s}{r} = 1$, then ϕ_0 is y_0.

(To be continued.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *Dec.* 31*st*, 1887.

Not long since a meeting of telephone experts connected with the American Bell Telephone Company, and its sub-organisations, met in this city to discuss in a private, informal way, the best types to be adopted in telephone cables. Owing to the fact that during the discussion various new ideas, more or less patentable, were brought to notice, it has been decided not to publish the report, which has therefore been printed for private circulation only. The practical result of the conference was so good, that another of a similar nature has just been held, with the object of discussing the most desirable forms and arrangement of exchange apparatus. This subject has been given peculiar prominence to by the many difficulties encountered in equipping the big new switch-board for the Metropolitan Company in this city, to be placed at the top of its handsome new building in Cortlandt-street. Some idea may be formed of this board when I mention that it is divided into 44 sections, and will have a capacity up to 10,000 wires, although at present the working equipment will be limited to 6,000. This board will have a length of about 300ft., and will be arranged in the shape of a square U. In order to make the connections, considerably over one million soldered joints are necessary in the board, and over 3,000 miles of wire and cable are being used. At one time more than 100 men were at work on the board for two months steadily, and the regular work has gone on for several months without intermission. The board was already nearly ready for work when the wholesale undergrounding of the telephone wires throughout the city led the company to make all the circuits metallic. This involved many changes and much new work, and a total expense to date of over £60,000. As may be imagined the construction of this board brought to light many new problems, and its progress to completion has been anxiously watched by large exchanges all through the country. It is at this juncture, therefore, that the second conference mentioned above has been fittingly held. It was attended by such well-known experts as T. D. Lockwood, E. J. Hall, jun., W. Wiley Smith, J. A. Seely, B. E. Sunny, E. M. Barton, C. C. Scribner, H. Metzger, and others, and its deliberations are understood to have been productive of much good in the way of suggestions and eliciting the experience of many years of work in this special work. One result arrived at, it is said, is the decision that, in spite of the many obvious objections, it is desirable in large cities to combine all the wires and connections as much as possible under one roof up to the number of at least 5,000 subscribers. Beyond that point, the conclusion seems to be it is better for the present to relieve the central office by a system of minor exchanges. The proceedings of this conference will, as in the other case, be printed for private circulation.

I believe note was made recently in this letter of the work proposed by the Lighthouse Board in connection with lighting buoys by electricity. The first experimental work of the kind

Digitized by Google

is at once to be carried out in New York Harbour with Edison 50 candle-power lamps, and Bishop gutta percha cable. The Board proposes to ascertain whether in the first place it is practicable to light the buoys at all in this way, in spite of storms, ice, &c., and whether it is possible to use the earth as a return. The Board also promises itself to make some inquiries into the conducting capacity of cables for this and similar work. It is evident that here, as in the case of the experiments in England in regard to communicating with lightships, some very interesting and important work has been undertaken, and the results will be eagerly awaited.

Indications are not wanting that considerable strides will be made during the coming year in the department of thermo-electricity. A recent development in this line is that of Mr. E. G. Acheson, of Pittsburgh, who, in order to increase and maintain differences of temperature between the two elements so as to secure a corresponding difference of potential, separates the elements by a moving conducting fluid, and applies heat directly to one of them so that the temperature of the other element can never rise above the boiling point of the separating fluid. Thus, while the element to which the heat is directly applied may be raised to a high temperature, the other element will remain comparatively cool, and thus a current of fair electromotive force will be obtained in the external circuit. Another point is that owing to the movement of the fluid the accumulation of gases on the surface of the solids is prevented, and thus a diminution of the current from this gas does not take place. In another form of this apparatus Mr. Acheson used a heated gas instead of the liquid as a conducting medium. In thermopiles as usually constructed two dissimilar metals are used, but in this apparatus only one kind of metal is employed. It may strike the reader as rather singular that in one form of this apparatus water or some such liquid should be used as a conducting medium, and that in the other a gas should be resorted to, but it will be remembered that gases when heated become far more conductive electrically. Very few details are yet given or obtainable as to the work of this apparatus in its most recent forms, but it would seem, if put in practicable shape, to provide means for the extensive utilisation of waste heat, in the form of current that could be stored.

There does not appear to be much that is new to record in the line of secondary batteries, except that considerable use is now being made of them in work where a year ago their employment was regarded as inadvisable, and even out of the question. There is no doubt that during 1888 plans now being projected will be carried out for the use of secondary battery plants on a large scale to be used either independently or in conjunction with central lighting stations now in operation. No small amount of work is also in hand in connection with street railway work, and the number of storage cars running on the streets will soon be very largely increased. Some little interest, by the way, is taken in the animated controversy which has sprung up between the Julien Company and the Electric Car Company, of America, operating the Reckenzaun system, as to whose car can make the best record. The Reckenzaun car on the trial tracks at the works at Philadelphia has made a record of over 63 miles with one charging of its batteries. The Julien car running on the Fourth Avenue line in this city, and traversing up town some of the roughest street car tracts in Christendom, has a record of over 40 miles to its credit, and is, I may add, now in daily service on the road, doing, it would appear, very good work. Each company is very well pleased with the results obtained, and with the better records that can be made without much effort; and it is whispered that each is willing to back its own car, so that it would not be surprising if some sort of challenge comes out of the dispute. Possibly, as in the case of the projected race across the English Channel by storage boats, the race will not take place; but this controversy will at least serve the purpose of calling attention to the marked improvements and advances that are being made in electrical street railway work.

While speaking of secondary batteries I may mention that Mr. A. V. Meserole, of this city, who has done quite recently some experimenting, reports that a good battery can be made, with carbon as an active absorbent, by the use of such carbonised vegetable substances as bamboo or boxwood, pulverised, and mixed in varying proportions with graphite, and then pressed into porous pots or bags. The material is worked into a paste with acidulated water, and then compressed into the porous envelope with a number of conducting plates or rods composed of an alloy of lead and antimony amalgamated. The usual grid may also be filled in with this plastic material, and then wound around with asbestos tape or cloth to prevent its erosion. The capacity of the element may be increased by the addition of oxide of lead to the mass forming one electrode, and the same may be said of the addition of oxides of various other electro-negative and electro-positive metals to the respective secondary poles, though this method brings back, of course, the objectionable features which the use of carbon is intended to avoid. Such a grid as he proposes, says Mr. Meserole, would have a constant conductivity, and would be practically indestructible with the use of any sort of electrolyte.

Reports come from Richmond that the Sprague electric road there is beginning to assume good shape, and that before long it will be in excellent running order. This road is a difficult one to operate by any system, and is also extensive, no fewer than forty electric cars being required in all. The Sprague Company is now busily engaged getting ready the equipment and forwarding it.

Over in Brooklyn the Van Depoele Company have just put a nice road in operation running from the outskirts to the suburban town of Jamaica, a distance of six miles. This road has practically no grades, and very few curves of small radius. It also has the advantage of running along what is still, to all intents and purposes, a private toll road, where civic authorities, with their prejudices, absurdities, and hungriness after backsheesh, cannot easily intrude. Another advantage is to be found in the fact that the road runs through a region which is being rapidly filled up by the overflow of the population from the "city of churches;" but perhaps the greatest advantage of all is to be found in the fact that it skirts about half a dozen cemeteries, and is bound to do an enormous business on Sundays, as well as every holiday of the year. At the stables of the company on the road, shoulder to shoulder with some of the new electric cars, are to be seen some of the oldest street cars used in this country, and the contrast speaks volumes. The Van Depoele people have also excellent reports from their road at St. Catharine's, Ontario, operated by water power from the Welland Canal. This road is about six miles long, and the secretary of it reports that the system, besides giving great satisfaction to the public and his company, is effecting an economy of about $18 a-day, as compared with the previous animal service. From Mansfield, Ohio, comes encouraging news of the operation of the Daft system there on a road about 4½ miles long, with five cars in use. Altogether prospects of the electric railway are very bright.

The efforts of some of our largest cities to put into the hands of the authorities the supply of electric light continue unabated, and are perhaps being made with more energy than ever. In Philadelphia, where it might have been supposed the results with the City Gas Trust would have been a sufficient lesson and warning, it seems to be the resolve of a large section of the community and of some members of the City Council to throw the electric lighting companies out of business. At the last meeting of the Common Council there it was proposed to cut out the appropriation of some £30,000 for public electric lighting, and notice was given to bring in an ordinance, providing the city should build its own plant, estimated to cost about £80,000, to supply 1,500 arc lights. Of course, such a proposition was warmly combated; but at the meeting for the award of the contracts a few days after the same spirit of opposition made itself manifest, and delay was secured in awarding the contracts. The new bids from the old companies cover about the same territory as before, but offer a reduction of about 4½ cents per

Digitized by Google

light per night, making a total reduction for the year of about £1,700. The companies interested, which form what is known as the Electric Trust, being all practically under one management, consider that they have offered fair and reasonable rates; but the opposition is still after their scalps, and it is probable that, even if the contracts are awarded, more will be heard about this matter.

CORRESPONDENCE.

THE SWAN FIRE-DAMP INDICATOR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the description of the Swan fire-damp indicator of the 23rd December, 1887, there is no mention of a screen of gauze to enclose the platinum spiral.

The action of the apparatus in question is based upon the combination of hydrogen and oxygen gases, which is promoted by heated platinum, and is the principle of an apparatus which I designed for the same purpose some years ago.

During my experiments with this apparatus I found that the platinum, after having been frequently heated by the gas, acquired the property of causing the combustion of the gases when not being heated by the battery current, and of itself becoming incandescent and exploding the mixture when gas was present in explosive proportion, and further of not indicating anything in pure coal gas.

It appears to me, therefore, that some considerable care must be exercised in waving about such an apparatus in an explosive atmosphere, in the manner described for charging Mr. Swan's indicator.

A less dangerous expedient would be to take a sample of the air to be tested in an india rubber syringe and perform the operation cautiously on the ground.

It is mentioned that a red hot wire produces these effects; but it is not necessary that the wire be red hot. A warmth just perceptible to the finger was all that was necessary in my fire-damp indicator, and the platinum became more sensitive with use, two good Daniell cells being all that was required to operate the apparatus.

That some misconception exists as to the temperature required for this kind of combustion is evident from a description of my apparatus which appeared in *Engineering* at that time, and in which the writer, who had never seen it in operation, described it as impracticable on account of the difficulty of maintaining the current necessary to heat the platinum. The current required had actually been furnished by a very small battery for some months continuously by day and night.

There are other conditions under which coal gas will ignite without the wire being heated; for instance, if a proper mixture of gas and air, slightly warm, be directed from a jet against a roughened edge of platinum foil, it will ignite, and if the mixture be a little warmer still, it will act in the same way upon the edge of a similar piece of iron.—Yours, &c.,

17, Cornhill, E.C., 11th January, 1888. F. HIGGINS.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

MR. EDWARD GRAVES' PRESIDENTIAL ADDRESS.

The first meeting of this Society for the present year was held at the Institution of Civil Engineers yesterday (Thursday) evening, January 12th, when the new president, Mr. E. Graves, Engineer-in-Chief of the Post Office Telegraphs, delivered the following address:—

According to the poetic mythology of ancient Greece, Minerva, fully grown and armed, sprang from the brain of Jove; Wisdom was perfect at its birth; neither study, observation, nor experience were necessary to bring it to maturity.

But the wisdom of the early civilisations dealt only with the external aspect of the material things. The hidden secrets of Nature were undisturbed. The philosophers of those days forebore to look below the surface, nor did they call into activity forces dormant until the moment that the researches of the investigator should stir them into life.

When that period arrived it was manifested by progress in a very different manner from the sudden growth symbolised by the myth of Minerva. First, the observance of strange phenomena, and of the fact that their reproduction, under similar or differing conditions, as the case might be, was possible. Next, the discovery of distinct purposes that could be effected, by the utilisation of the same force that had given rise to the phenomenon originally observed. Then, the knowledge of the means by which this force could be produced, to whatever extent it might be required or be capable of, and that when produced it could be controlled; and lastly, the combination, into a definite scheme, of the results of all these researches and discoveries, so that the principles regulating the new science might be formulated, and its leading laws made known—thus creating a basis upon which could be ultimately moulded a more or less valuable addition to the resources of the human race.

The various stages through which the growth of any original science must necessarily pass can be stated in a brief paragraph, but to realise them centuries are often required.

Electricity and magnetism (which may be regarded for our present purpose as varying expressions of the one original power) furnish a clear illustration of this fact. Even now our knowledge, both of the agent itself and of the possible uses to which it may be applied, is very incomplete; but being what it is we can clearly trace its evolution.

Neglecting the earlier observers, who merely noted the existence of startling facts which they neither endeavoused to reason upon nor explain, we may fairly say that from Gilbert, of Colchester, to Faraday, three complete centuries were occupied in nearly continuous investigation of the laws that govern the action of the mysterious agency, and of the methods by which its powers could be controlled and employed. A long list of names of distinguished men in all civilised countries shows that many minds co-operated in the inquiry, and aided to piece together, observation by observation and discovery by discovery, that mighty outcome of scientific origin which, in many respects, has revolutionised the material world, and will still further—how much further one dares not say—influence its destiny.

Faraday and Joule may be regarded as the last workers and discoverers—of English birth, at least—in the field we are considering, who trod its path with absolute devotion to pure science alone. They and their predecessors noted facts and deduced principles; they stored up a mass of observations for the guidance of their successors, but they did not seek to apply them so as to turn the knowledge that had been gained to commercial account.

A different state of things now exists. Long prior to Faraday's decease other earnest students of electric science saw that in realising the triumphs that it might attain, benefit might be secured to their race and to themselves alike. The hour had come when the labourer could reap the reward of his efforts, and profit by the devotion of his life to the study of Nature's laws. Since then, every distinguished electrician has applied the science he loves to some practical purpose. When success has been secured in one department it serves only as a spur to further exertions, seeing that success means reward, and thus the recurring stimulus produces greater and greater efforts, and wider and more far-reaching results.

The object of the compiler of this address has been, however imperfectly, to trace the nature of the benefits already conferred upon the world by the use of electricity in some of its varied expressions, and to gauge the extent of the employment it has given by means of its operations, to at least the inhabitants of our own country.

It is almost impossible to express the variety of ways in which the action of electricity is utilised. Their name is legion, and they are ever multiplying. Communication between distant places was the first widely extended purpose to which it was practically put. Originally its operations were confined to points separated by land only. Then intervening rivers, channels, seas, and oceans were successfully crossed, until now nearly the whole earth is bound together by submerged chains—a kindly bondage that is another name for union. One ocean only—the Pacific—remains uncrossed, and the barren distinction will hardly be much longer preserved. One country of importance only—the Empire of China—has hitherto been reluctant to encourage the lightning messenger, but that reluctance appears to be on the verge of disappearing.

Another most prominent utilisation of electricity is for the purpose of illumination. First practically discovered by Humphrey Davy, its powers in this direction were successively made practical by Wylde and De Meritens, Pacinotti and Gramme, and by many eminent scientists of later date. Electric lighting has passed very many stages. Differing from telegraphy, it needed a longer period of trial and experiment after its commercial application began; and it is, of course, exposed to the competition of other illuminants ever seeking, by new methods, to lessen its superiority. Economy of production is, perhaps, the great necessity for its complete development. As the light of brilliance, health, and beauty, its claims are universally acknowledged; but the commercial problem can hardly be said to be yet completely solved, although the steps taken in that direction give promise of a satisfactory solution being not far off; the problem of distribution is becoming understood.

Telephony—in other words, telegraphing by means of the sonorous vibrations of the human voice, and not by means of signals controlled by the human hand—came into the field comparatively recently, but has met with wide acceptance, and has had a vigorous growth. It has been welcomed in all countries as a boon to humanity. The delicacy of the instruments by which it is worked is, perhaps, the source of greatest difficulty that its further development has to overcome; their sensitiveness

is alike manifested to intended and unwished-for influences. Since their inception we have had means of observation far more delicate than any previously in general use, but we have also discovered that the influence of "induction" is apparent to a much greater degree than was before deemed probable as an interference with the practical working of electric communications for commercial purposes.

In electro-metallurgy, electro-plating, electro-typing, and the like uses, electricity operates in many different directions. In some branches it is employed as a new and better way of producing the same results that were previously produced by inferior means; in some the results attained are novel, as well as the methods employed.

The substitution of electricity for steam, water, or gas, as a source of power, capable of driving mechanical engines, either stationary, locomotive, or marine, and the transmission of similar power to a distance from its source of origin, although successfully carried out in many important instances, may be considered as yet rather in the earlier stages of experiment and growth than of those of completion. There is a wide field yet to be explored in this direction.

For medical purposes electricity is also extensively employed; but I confess that I am unable to separate the wheat from the tares—the really curative agent from the imposture—and therefore can only say that it is evident that much may be done in this direction; much is already done, but the extent of the area it will finally occupy cannot yet be perceived. When the real nature of the power employed is understood, then we can better appreciate the nature of its influence upon the ailments to which the human frame is subject.

As a warning against fires that may threaten our houses, an agent employed to summon helpers to our relief, the electric current renders great service, that will, it is to be hoped, be availed of more extensively in the future than it is at present.

Electricity is also utilised to an increasing extent as a safeguard to the lives of the toilers in our coal mines charged with explosive gases. As yet it is somewhat in an uncertain stage in this respect—its use is proved, the desirability of its employment recognised, and efficient instruments for the purpose devised, but practice is yet needed to remove the difficulties in the way of its general adoption, to overcome the inertia that blocks its path.

Like the steam hammer that can strike with the weight of many tons, or crack a nutshell with a gentle tap, electricity can unite sundered continents or serve as a household convenience. For ringing the bells of our houses it has practically superseded the apparatus of pulleys, cranks, and movable wires; it can be operated over distances to which they were inapplicable. For submarine mining, blasting rocks, firing discharges that cause mountains to crumble, and for the purposes of warfare, the heat-conveying powers of electricity are extensively employed.

The last of the uses of electricity that I will particularise was one of the earliest to be availed of—a species of telegraphing with a special object, guiding trains on their way, and guarding against the risk of collisions by night and by day. When steam had won its greatest victories, it was necessary that some swifter and more subtle power should be at hand to control and regulate its action. Such power was found in the use of electricity, by means of which signals are given that track and guide the moving train throughout its journey. The line of railway is divided into successive sections, into each of which a train is forbidden to enter until the electric indicator gives permission, such permission being withheld until it is announced, by similar means, that any preceding train has passed from the further end of the section, upon which its successor is allowed to enter.

I have so far specified a few of the leading purposes for which electricity is employed, but to enumerate them all is practically impossible; the sphere of its influence is widening every day, and no one can attempt to say when its ultimate limits will be reached.

Only on Saturday last I saw an announcement in an evening journal to the effect that it had been discovered that the passage of a powerful stream of electricity through sewage water effected the division of the solid from the liquid constituents of the latter. No practical description of the *modus operandi* was given; but the bare announcement, whatever the results, shows a new direction in which some minds, at least, hope that profitable employment for the electric agent may be found.

It is clear, however, that in the great majority of its applications electricity is used as an agent—a tool, so to speak—for producing effects hitherto obtained less perfectly and less extensively by other means. For illumination, the supply of power for plating and many other purposes to the production of which electricity is applied, means existed in one form or other before the use or value of the latter was known. The improvement, however, effected by its use in some processes has been so great that it amounts almost to a discovery, and in almost all there is still great scope for increased progress.

One of these processes may be mentioned in the case of the electric light as applied to the illumination of ships—notably passenger steamers—at sea. The contrast between the comparatively dim oil lamps and the bright glow of the incandescent lights is so great as to make the latter really a new thing. Gas cannot, for self-evident reasons, be commercially applied to our floating palaces. Electricity has therein found a field in which it has no competitor.

Telegraphy and telephony, however, have introduced a really new thing into the world. True, the word "telegraph" was applied to an instrument—the semaphore—which preceded that which we mean when we use the same expression; but its operations were so limited—darkness or fog suspending them entirely—that no real comparison between the apparatus of Wheatstone and Morse and their so-called mechanical predecessor can be instituted. A few lines of gaunt-looking frameworks, on which hung pendant legs and arms of wood, or closing and opening shutters worked by levers, stood at considerable distances from each other. The signals expressed by the persons controlling the first machine in any such line were noted by an observer stationed at the next machine, through a powerful telescope; from the second they were repeated to the third; and so, when the light and weather permitted, they reached the final point communicated with, sometimes with very considerable rapidity. Nearly all such lines—and they were not many in England—were entirely for the Government service, chiefly that of the Admiralty. The only long private line of communication of the kind of which I am aware was that belonging to the Mersey Docks and Harbour Board—from Birkenhead to Holyhead—used for signalling the arrival or departure of vessels. Imperfect as such means of communication—often interrupted—were, when their operations *did* succeed they were enough to show how great the advantage would be to the world in general if they could be permanently depended upon. Hence arose the efforts of Ronalds, Sœmmering, and others; but the time was not fully ripe. The discoveries of Galvani, Volta, and Œrsted, however, combined with the result of preceding experience, led to the construction of the telegraphs of Gauss, Weber, Schilling, and Steinheil; and, finally, the endeavours of Cooke and Wheatstone in England, and Morse in the United States, resulted in the production and general use of a reliable means of long-distance telegraphy, which has since been improved upon in many ways, but which, in its essentials, remains the same.

Now let us see what is the outcome of all this thought, inventive genius, and intellectual energy. What has the thing they produced done for us?

Let us compare, say 1837—when Cooke and Wheatstone first demonstrated the practicability of their system—with the facts of 1887.

In 1837, whenever a member of any family, however highly placed, left the shores of his native country, he was lost to his friends—he disappeared, as it were, from their lives. He might be heard of at more or less frequent intervals by correspondence passing through a slow post, but in no emergency, however great, could he be communicated with in time to admit of his taking prompt action; separation was realised and its real meaning felt. For instance, in 1834—and the conditions were little changed in 1837—when the first Melbourne Administration was dismissed by King William IV., a special messenger, despatched from Brighton on the morning of November 15 to Sir Robert Peel, then at Rome, could only carry to him the offer of the Premiership in ten days' time; making all possible speed he only arrived on November 25.

At the present day let a man travel throughout the world, he holds in his hands, as it were, the strings communicating with his own home. Twenty-four hours, in practice, is an extreme period to elapse between the despatch of an urgent summons, or the communication of an important piece of intelligence, and its acknowledgment by the recipient, even at the ends of the earth. Last month Lord Hawke died at the St. Pancras Hotel. His son and successor was cricketing in Victoria, Australia, but in a few hours he received the sad intelligence, and will be home long before he could have known of the necessity for his return in the former state of things. Take the converse of this case. A criminal fleeing from justice wishes, of course, to cut off all traces of his connection with the place whence he flies. Fifty years ago he could do so easily; a few hours' law at the start would enable him to elude pursuit effectively. He could escape by sea and know that he could not be followed for a certain number of days, and that on his pursuers arriving at the foreign shore they would find him gone—vanished into the far-spreading regions of the West or South—where no clue could be found. Now let a man succeed in catching the fastest steamer that skims the ocean, and let him do so unobserved by his trackers here, he arrives at New York, Cape Town, Sydney, Melbourne, or Suez, only to find the police awaiting him, and ready to return him, by the quickest available means, to answer for his misdeeds.

In some quarters there is a tendency to question whether our modern improvements have really tended to increase the happiness of the world; whether there was not more real comfort when the pace was not so fast. A recent novelist has entitled one of his last productions—the period of which is laid in the last century—"The World Went Very Well Then," implying, of course, that the present day is, at any rate, very little better; this is not the general feeling. There may be a germ of philosophic truth in it, but mankind does not, as a rule, govern itself by philosophic ideas. It may have been possible for a merchant of 50 years ago, who knew nothing of the changes of markets or of the political occurrences that had happened which might govern them, or affect speculative risks, save on the arrival of weekly, fortnightly, or monthly mails, to be content that he was spared the worry of concerning himself every day with such matters; but now the telegraph brings him daily or hourly news. On all these points he has, at least, the advantage that no catastrophe can mature during his period of ignorance, and burst on him like a thunderstorm when the periodical notification arrives. Counting-house speaks to counting-house, not face to face, but in effect almost as if it were so. Orders have been despatched by post to be executed in London, and the goods sent to Calcutta; a turn of the market at the latter place shows that the execution of the orders will be a misfortune; the telegraph is employed and they are countermanded, no mischief being done. Shares that are held in various parts of the globe are suddenly greatly appreciated or depreciated at one of the great commercial centres: the facts are at once transmitted by wire to the others, and all markets are, at nearly the same time, placed on the same footing. The possibility of dealing rapidly in one centre, and of perhaps reversing the operation in another, is rendered, under ordinary conditions, impossible; no such *coup* as that by which Nathan Rothschild gained £2,000,000 by his energetic exertions to secure early intelligence of the result of Waterloo is now possible. To a large extent individual chances are equalised, at any rate so far as they depend upon the securing of rapid knowledge of occurring events. It is argued that this is an evil to the smaller firms, that houses with a large command of means can bear the cost of communicating freely by wire, and thus the possession of capital

tells more heavily than before in the race of competition against the lesser houses. There is some truth in the contention, but it is but one illustration of the general tendency of modern trade, which more and more shows that success in all the wider fields of commercial life is mainly secured by the operation of gigantic concerns working with vast resources, whether wielded by a single person or by an association. Individuals suffer in this struggle of competition, but the world at large profits by the increased magnitude of the aggregate business done ; and the facility of rapid communication is not the least potent factor in bringing about the results we are witnessing.

In political matters the lightning messenger is not less powerful for good. Formerly, intelligence of some disturbance or menacing event was received at headquarters on a certain day, and nothing could be heard in reply, nor any direction given, until many successive events had transpired, and perhaps irremediable mischief had been done. In its early days, also, to put the telegraph in motion was of but doubtful advantage ; the despatches were too brief, the orders were too curt—they were often misunderstood—rarely was their motive explained. In later times it has been found possible, on sufficient occasion, to exchange by telegraph despatches as full and clear as could be transmitted by letter, and thus no ground is left for the growth of misunderstandings that might produce international evil. Formerly irritated feelings grew up, and those whose duty and desire it was to soothe them were too late before they could apply any effective check to the popular passion that was urging either side into courses that could only culminate in war. The excitement that convulsed this country when Commodore Wilkes forcibly took the Confederate envoys from the mail steamer "Trent," and very nearly brought two kindred nations into a miserable conflict—there being then no cable connecting England with the United States—and the speedy collapse of the fierce fever that overspread France this year, when the frontier squabbles with Germany culminated in the forcible arrest of Schnaebele, followed later by the unfortunate shooting of French sportsmen by Germans, are instances of the advantage of the telegraph being in existence. The statesmen on either side were enabled to promptly calm the feelings that threatened much at first, but speedily collapsed when the trifling character of the unlucky accidents was understood. Perhaps the ease with which directions can be transmitted from the centre of Government to colonial governors or military commanders should be admitted to have some drawbacks attaching to it. Of course the full circumstances of any special situation can only be known to those absolutely on the spot, and it is an evil when the transmission of too detailed instructions to them destroys the sense of individual responsibility in the officers commanding abroad. The telegraph makes much possible for the Minister at home, but in some things discretion is best shown by abstinence from its too extensive use. Again, to take another form of superfluous energy as an example, it was, to say the least, unfortunate that, when the British and French armies were engaged in a life-and-death struggle with the Russian foe in an inclement winter in the Crimea, Lord Panmure, the then Minister for War, found the single wire laid between Varna and Sebastopol convenient for desiring the English Commander-in-Chief to "take care of Dowb"—his relative, Major Dowbiggin.

News, in its widest sense, is a very different thing now than it was formerly. A newspaper of the earlier portion of this century contained intelligence from all quarters, no doubt, but it was not contemporary intelligence, nor at all regular in its appearance. From the nearer capitals of Europe it might perhaps be two or three days old only, but in the same journals that printed this news appeared articles from the more distant parts of the globe dated two, three, or even five months before. For instance in 1837, in *The Times* of July 20th, there appeared news from Valencia, Spain, of Carlist operations on July 15th ; the semaphore having been utilised for its transmission across France, but its news being broken off because darkness had come on. On July 26 news was published from Rome dated July 16th. On the 28th of that month the dates from Hamburg were July 23rd ; but in the same issue Constantinople intelligence of July 7th was printed. From Quebec, news to the 3rd July did not appear until 3rd August ; and from New York, May 4th is the latest date mentioned on May 29th. From Tasmania, news to January 27th was not made known until May 30th. From the Cape of Good Hope, intelligence to March 25th was not published until May 30th ; and on the same day Calcutta advices to January 27th appeared. Sydney letters of December 31st, 1836, were made public on June 8th, 1837 ; and, in the same paper, Batavia reports of December 28th preceding appeared. Buenos Ayres news of March 19th saw the light on June 13th.

In an earlier issue of that journal, under date of December 10th, 1834, appears a paragraph calling attention to an instance of unexampled rapidity of communication between Liverpool and New York, letters having crossed the Atlantic three times within 65 days. The vessels conveying them made unusually quick passages, and each departure took place within a few hours of each arrival, the correspondents taking advantage of them to despatch their communications without loss of time.

Since that period an entire change has appeared on the face of journalistic matters. If a cricket match takes place at Sydney, New South Wales, on December 10, the full score appears in *The Times* on the morning of December 12, the intervening day being Sunday, but 10 hours being represented by the difference of time between the longitudes of Sydney and London. On December 23 a resolution of the New Zealand House of Representatives, on the subject of Colonial Defences, dated December 22, appeared in the first edition of the same journal. And on December 31 a message appeared in the second edition of the *Globe*, printed at 12:30 p.m., dated the same day, giving the substance of Mr. Chamberlain's speech at a banquet at Toronto the previous night. If despatched at 6 a.m., the difference of time alone would make it five hours later before it could reach London.

Not only events of mighty import to the interests of nations, but records of comparatively trifling matters—the appearance of a popular actor, the result of a boat race, and the like—are flashed across the world, and published here as they would be had they transpired in some city of our own island. The world has indeed become very small, if its dimensions are to be measured by the rapidity of knowledge in one part of the facts that occur in another.

Again, as regards our own country alone, a most remarkable change has occurred in the character of the press. Fifty years ago the most important speeches might be delivered a few hundred miles from London, and they appeared in the shape of a meagre, condensed summary the second or third day after delivery. They were no longer new when they could appear at all, and hence it was not worth while publishing them at length when they did appear ; perhaps, however, this imperfect publication had the compensating advantage of lessening their frequency, so far as readers were concerned. Now, if Mr. Gladstone speaks in Midlothian, Lord Hartington at Dublin, or Lord Salisbury at Liverpool—although it may be close on midnight before their oratorical efforts are completed, yet next morning the broad sheets of our daily press will give us, verbatim, all that their audiences have listened to ; and, in fact, the readers of London papers often know much earlier than the residents of a village ten miles from the place where the discourses were delivered what were the very expressions of the distinguished speakers.

It is not, at the present day, conditions of time or distance that limit the fulness with which an oration appears, the morning after delivery, in the newspapers, but only the amount of popular interest which the conductors of each particular journal believe will be taken by its readers in the speaker's words. Audiences are no longer confined to those who can be present in the largest halls ; on the wings of the telegraph, and by the agency of the newspapers, the speaker addresses the whole world, or at least such portions of it as care to know his opinions on the subject of which he speaks.

(To be continued.)

THE POSITION AND PROSPECTS OF ELECTRIC LIGHTING IN THE METROPOLIS.

On Tuesday evening Mr. W. Lant Carpenter, B.A., B.Sc., Manager of the School of Electrical Engineering in Hanover-square, read a paper at the monthly meeting of the Middlesex Natural History and Science Society, at the Society's rooms, 11, Chandos-street, Cavendish-square, W., "On the Position and Prospects of Electric Lighting in the Metropolis." There was a crowded attendance, and the room was lighted by the Union Electrical Power and Light Company. The Earl of Crawford had been expected to take the chair, but was prevented from doing so by a political engagement at Wigan. Letters and telegrams were read from other gentlemen, regretting their inability to be present.

Mr. Arthur Coates took the chair, and the lecture was amply illustrated by experiments and lantern illustrations. The chairman having briefly introduced the lecturer, Mr. Carpenter began by a brief comparison of the means of producing, storing, distributing, and consuming gas and electricity for lighting purposes. In reference to the use of primary batteries being limited by cost, he spoke specially of the Upward batteries, and sketched the development of the dynamo from Faraday's discovery, the main point in connection therewith being the following figures :—

Comparison of a 1,200 Light Dynamo 1882 and 1887.

	1882.	1887.
Weight	44,820lb.	11,760lb.
Bulk	320 cub. ft.	180 cub. ft
Absorbed H.P.	154 H.P.	112 H.P.
Commercial efficiency	67 per cent.	93 per cent.
Price per 100 watts output	£29	£6
Price per lamp	£2	7s.

In nothing, he said, was the progress in five years so remarkable, and one could not reasonably expect much greater commercial efficiency. Pointing out the difference between direct and alternating current machines, the lecturer said the principal examples of alternating currents were at the Grosvenor Gallery and Paddington Station, and the disadvantage of that was that they could not use secondary batteries, without which he did not consider that any installation of electric light was complete. He briefly traced the history of storage batteries and spoke of the E.P.S. cells and the Union cells. He pointed out that a low tension current required large and costly conductors, while a very small wire sufficed to carry a high-tension current. The use of transformers was then described and illustrated : by the use of these instruments high-tension currents brought from a central station by small wires were transformed down to low-tension currents at their entrance into houses, and thus risk was avoided. He then went into the question of overhead and underground conductors and the distance limits of the distribution of electricity, which could be set down practically as not exceeding two miles for commercial working, and probably nearer one. In reference to arc lamps, these had improved very much in steadiness, but the Brockie-Pell was the best, as being practically perfectly steady. As to glow lamps, their construction was briefly explained, and attention was called to their improved light and the greater number of hours they lasted. With reference to London lighting by arc lights, probably most had been done by the Brush Company, who thought that as to semi-public lighting of a permanent character there was no better instance than Charing-cross Railway Station,

which had been lighted from their works on the opposite side of the river for the last six years; also Liverpool-street, Waterloo stations, and the South Kensington Museum, in which last place, according to the official reports, the cost of gas each year would have been more than double. In the Colonial Exhibition the Company had 160 arc lamps, 18 in the garden, and 16 for the fountains. Negotiations were going on between that Company and the Corporation for the lighting of a very large area in the City of London. The Thomson-Houston system was rapidly gaining ground, and was worked by Messrs. Laing, Wharton and Down. At the American Exhibition they had 285 two thousand candle-power lamps, and there was not a hitch the whole time of the Exhibition. Longer established and nearly as large was the Gülcher Company, which had had 125 two thousand candle lamps at the Crystal Palace for nearly four years, and they now had 40 arc and 200 incandescents at the Aquarium, and 68 arc at the Olympia. For alternating current arc and glow lighting, Paddington Station installation, visited in October by the Society, and the Grosvenor Gallery were almost the only examples. In incandescence lighting, driven without accumulators, they had the Brush Company supplying the Grand, the First Avenue, and the Métropole Hotels, and many thousand lights in different parts of London. The Gülcher Company made a speciality of supplying photographers with electric light for their work. The Maxim-Weston Company were putting down in the north of London a large installation of fifty arc lamps and 400 incandescents, which when complete would be the largest, or one of the largest, private installations in the suburbs. They were negotiating about a central station in the city, and the manager of their works said:—"I can assure you that the electric lighting industry, in my opinion, never looked brighter than it does at the present moment. If the prospects improve in the same ratio as they have done in the last four months, there will be a very wide field next year." Messrs. Woodhouse and Rawson had lighted many printers' and large shops, such as Shoolbred's. A typical instance of domestic lighting, by Messrs. Woodhouse and Rawson, was the house of a well-known surgeon, who had 40 lamps specially arranged for lighting pictures as well as for making examinations of the eye with the opthalmascope, and the cost of gas for driving the engine for one year was £12. The same firm had carried out a curious installation in the sewage tanks at Crossness pumping station, which had to be cleaned out every twelve hours, and in which the atmosphere was so bad that candles burnt with difficulty. Referring to the lighting of theatres, the lecturer thought it essential that in any theatre the light should be put in two circuits entirely distinct, so that if anything went wrong in one, the place would not be in darkness, and so a panic would be avoided. A large installation of 5,000 lamps was being put in a large building in Whitehall, and a new system of distribution was being tried there by Mr. J. E. H. Gordon. As to installations in which accumulators formed a necessary part of the system, in the city the E.P.S. Company had more than 3,500 lights, and the use of accumulators was indispensable, since gas engines were nearly always employed, and when they are employed the light direct from the machinery was irregular. Among the prominent installations of this company were mentioned the Royal Society, the Bank of England, Lloyd's, offices of the P. and O. Company, and six banks. The largest thing Messrs. Drake and Gorham had done was the Prudential Insurance Company, with 2,500 lights, and when complete there would be 500 horse-power available, and 528 accumulator cells all in and for one building. After three years' trial the Bank of England were extending the lighting to all their principal offices.

The latest development was at the central station at Kensington Court, established by Messrs. Crompton and Co. It was the first station in London under the Electric Lighting Act, and it was extremely satisfactory in its financial results, the shares being now at 50 per cent. premium; and the company had decided to apply for powers to extend it over a very large area, comprising nearly the whole of Kensington, Knightsbridge, Brompton, and a portion of Chelsea, probably altogether the richest portion of residential London. The great feature was the small size of the plant and the space occupied by it in proportion to the work done. There was a special kind and special arrangement of accumulators, owing to which at present the steam engine and dynamo were never run after midnight. The engine employed was Willans' triple expansion engine, probably the most economical known. The cylinders were approximately 6, 8, and 12 inches diameter. The engine drove the dynamo direct at 370 revolutions a minute, and taken off the coal bill it burned 3½lb. of coal per electrical horse-power per hour. The combined engine and dynamo stood on a space 9ft. by 4ft. 6in, and there were three of them, each of which gave a current of 250 amperes. There were two boilers, by Marshall, of Leeds, 15ft. long, 4ft. diameter, which burned from 60lb. to 70lb. of coal per hour. At present there were 1,000 lights supplied, and 500 more were contracted for, all in private houses, each with a meter. The farthest house at present lighted was 900 yards from the station, and Mr. Crompton believed that he could supply houses two miles off. At the Kensington Court station there was room enough to supply 20,000 lamps. The charge was 8d. per Board of Trade unit, which worked out to, if one wished to be exact, 0·28 of a penny, which was practically a farthing per lamp per hour. In conclusion, Mr. Carpenter said:—"Reviewing the whole of the evidence before us, it may fairly be said that the electric lighting industry has reached a stage in which the prospects of its very speedy development are decidedly good. As knowledge concerning it is gradually diffused the public becomes familiarised with the conditions under which alone it can be successfully carried out. The experimental step has passed. The days when electric lighting firms were glad to put up a temporary, and in some cases a permanent installation, at much less than cost price for the sake of advertising themselves and the light are, let us hope, gone for ever. The cases of failure of the light now are exceedingly rare, and I say advisedly that there is no case of failure known in which the cause was not thoroughly understood, and where it might not have been prevented beforehand by the expenditure of a little more money on the plant, or on the salary of a more competent superintendent, or on both. The mischief done by self-styled electricians, often so called merely from having fixed a few electric bells, is well-nigh insuperable. The fact, too, that a few years ago electricity was a name to conjure with on the Stock Exchange, and the means of enormous sums being lost with the gambling that went on there, shook public confidence to its foundation. I regret to say that even at the present day there are certain company promoters, connected more particularly with so-called new primary batteries, &c., against whom intending investors and others interested need to be put upon their guard. Only a few weeks ago a former pupil of mine told me he had been the means of preventing a sum of money, measured in tens of thousands of pounds, from being thrown away on one of these bubble schemes. The legitimate work is steadily increasing, and, not only in London, but all over the country, manufacturers are looking forward to a rapidly increasing business."

A brief discussion ensued, and a hearty vote of thanks was tendered to Mr. Carpenter for his interesting and exhaustive paper.

THE LIGHTING OF THE CITY.

At a meeting of the City Commission of Sewers, held at Guildhall on Monday last, Mr. Graham King presiding, a report was brought up from the Streets Committee submitting for adoption a proposed arrangement with the Anglo-American Brush Electric Light Corporation for lighting a district of the city by means of electricity. It stated that for nearly four years the committee had been in negotiation with that company in reference to various proposals for the electric lighting of a portion of the city on the principle of their being afforded facilities for lighting the private premises on their line of route, and they now submitted a draft contract for lighting the district commencing from the front of the Royal Exchange, and comprising so much of the city as lies between the Poultry, Cheapside, St. Paul's-churchyard, Ludgate-hill, and Fleet-street, on the north, and Queen Victoria-street and the Embankment on the south. It was proposed to have 169 arc lamps of 2,000 candle-power at £26 each per annum, or £4,394 in all, in place of 616 gas lamps costing £2,246, the total illuminating power of the arc lamps to be about 32 times that of the present gas lighting. In the narrow parts and courts glow lamps or arc lamps of less capacity and in greater number might be substituted at an additional cost of 50 per cent. and 25 per cent. respectively. The contract was for seven years, with power to the Commission to continue it for further periods of seven years so long as they did not grant to other companies powers in regard to private lighting within the district. The contract might be terminated after notice in writing of insufficiency of lighting and non-remedy by the Company for a month. The Commission would grant to the company the exclusive right to supply private lighting, and if they terminated the contract as to public lighting the company were to be at liberty to continue their private lighting.—Mr. J. C. Bell, in moving the adoption of the report, spoke of the great importance of the matter, and observed that unless the Commission gave some such stimulus as was proposed in the report electric lighting in the City must be inoperative for some time to come. The cost would not be more than twice the present cost of gas, while they would have thirty-two times more light. There was a very general desire on the part of the ratepayers for the introduction of the electric light, and the district in question would be lighted at a cost of not more than one-eighth of a penny in the pound to the rates. The city was well lighted as it was, but compared with Paris and other Continental cities, where the electric light was in use, it was very badly illuminated. The committee had earnestly considered the question of lighting the whole of the city, but the cost of lighting the small bye streets made it very expensive. No doubt they were creating a monopoly, but unless some such concession was given they could not hope to have electric lighting in the city.—Mr. W. H. Pannell, though strongly in favour of having the electric light, urged that some stringent forfeiture clauses should be inserted in the contract. The Commission had had some experience in the matter, and had seen their agreements with other companies used entirely for Stock Exchange purposes, without any consideration for the public interest. In the proposed agreement the company were to be at liberty to continue the private lighting, although they might not be able to continue the lighting of the public lamps, which it was admitted would be supplied at a loss to the company. Thus the company, immediately they obtained the monopoly, would have the power of repudiating their agreement to supply the public lamps. Again, the company would not be bound to supply all who desired to have the light, and they could charge exactly what they liked. He moved that the report be referred back to the committee for further consideration as to the points he had mentioned.—Mr. C. T. Harris advised the Commission to exercise particular caution in the matter.—Mr. F. Green remarked that if the chairman of the committee would consent to insert a forfeiture clause the Commission were practically agreed upon the report.—Mr. J. C. Bell, in reply, said they were bound to take some risk in the matter. He thought the fact that the company would have to expend a large sum in laying down their plant should be a sufficient guarantee. No company would consent to the insertion of a money penalty forfeiture clause. Electric lighting had been sufficiently handicapped by Act of Parliament without the Commission throwing obstacles in the way.—The amendment of Mr. Pannell was carried by twenty votes to eight, and the report was referred back for reconsideration.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions*

17,863. ROBERT HASWELL. Hartlepool. Producing electrical energy by means of the revolving axles of railway carriage wheels. December 29, 1887.

20. J. SHERRIN and J. VAUGHAN SHERRIN. Ramsgate. The entire or partial propulsion of bicycles, tricycles, and velocipedes by means of electromotors worked by primary batteries (complete specification). January 2, 1888.

39. E. TYLER. London. An improvement in voltaic batteries. January 2, 1888.

40. E. TYLER. London. An improvement in electrical block indicators for railways. January 2, 1888.

41. E. TYLER. London. An improvement in voltaic batteries. January 2, 1888.

50. D. J. MORGAN. London. Improvements in ships' lights in connection with ships' mechanical or electrical telegraph systems. January 2, 1888.

56. J. Y. JOHNSON. London. Improvements in the manufacture of the incandescing portion or luminant of incandescence electric lamps (Theodore Mace, United States). January 2, 1888.

80. J. R. THAME. London. Electro-mechanical automatic apparatus for the sale of merchandise. January 3, 1888.

100. H. H. LAKE. London. Improvements in and relating to apparatus for generating electricity (W. Humans, United States). (Complete specification.) January 3, 1888.

112. H. F. JOEL. London. Improvements in incandescence lamp holders and switches (Complete specification.) January 4, 1888.

115. S. W. BAYNES. London. Improvements in the insulation of electric appliances. January 4, 1888.

121. W. HORSFIELD, H. HIBBERT, and S. HORSFIELD. Nottingham. Electric tree tubs. January 4, 1888.

137. J. C. PURTHNER. Vienna. Improvements of the apparatus for producing inducted electric streams in the same direction (complete specification). January 4, 1888.

155. A. J. BOULT. London. Improvements in or relating to electrical turnstiles. (Otto Ehrling, Germany.) (Complete specification.) January 4, 1888.

208. O. C. DALHOUSIE ROSS. London. Improvements in the utilization of waste products from electrical batteries. January 5, 1888.

COMPLETE SPECIFICATIONS ACCEPTED.

NOTE.—*All persons interested in opposing the grant of a patent on any one of the undermentioned applications may, at any time within two months from the dates in italics, give notice at the Patent Office in the prescribed form of such opposition.*

January 7.

1,654. W. KINGSLAND. London. An improved method of closing or sealing secondary battery cells. February 2, 1887.

2,851. T. PARKER. Manchester. A new or improved automatic switch or cut-out for electrical circuits. February 24, 1887.

3,197. Sir D. L. SALOMONS, T. PARKER, and P. B. ELWELL. Wolverhampton. An improved means of separating the plates in secondary batteries. March 2, 1887.

3,469. C. A. MCEVOY. Southwark. Improvements in electric primers and mechanism for firing breech-loading guns. March 7, 1887.

4,478. C. MAYNARD. London. Improvements in the mode of, or means for, supporting or carrying telegraph or telephone wires or lines. March 25, 1887.

11,448. J. S. SELLON. London. Improvements in secondary batteries or electrical accumulators. August 22, 1887.

16,669. M. BAILEY and J. WARNER. London. An improved secondary battery combined with a miner's lamp. December 3, 1887.

16,728. A. HEINTZ. London. Improvement in the manufacture of incandescent electric lamps. December 5, 1887.

PATENTS SEALED.

December 30, 1887.

12,222. R. J. RUDD. Croydon. Electric apparatus for indicating time. September 25th, 1886.

893. G. W. HOOK. Wood Green. An electrical billiard marking repeater and indicator. January 20th, 1887.

14,135. H. J. HAIGHT. United States. Improvements in electro-magnetic self-signalling, self-alarm, and self-recording thermoscopes. March 18, 1887.

January 3, 1888.

13,971. H. R. FISHER. London. An improved self-regulating electric portable battery and lamp. October 30, 1886.

16,440. W. J. MACKENZIE. Glasgow. Improvements in electric arc lamps. December 15, 1886.

16,662. R. P. SELLON, W. M. MORDEY, and C. E. WEBBER. Surrey. Improvements in means for automatically regulating electric generators. December 18, 1886.

16,942. J. D. F. ANDREWS. Glasgow. Apparatus for conversion of electrical currents. December 24, 1886.

SPECIFICATIONS PUBLISHED DURING THE WEEK.

15,774, 1886—I. PROBERT. Electrical switches, &c. (Price 1s. 3d.)

1,741, 1887—S. SUDWORTH, and C. K. FALKENSTEIN. Making and breaking electrical circuits. (Price 8d.)

1,862, 1887—C. D. ABEL. (Dun and Hasslacher.) Secondary batteries. (Price 6d.)

1,929, 1887—C. D. ABEL. (Dun and Hasslacher.) Galvanic batteries. (Price 4d.)

1,952, 1887—A. F. DEWAR, and F. WILSON. Electric switch. (Price 8d.)

1,993, 1887—E. HERMITE and others. Electrolysing bleaching solution (Price 11d.)

15,329, R. W. EDDISON. (McKnight.) Covering insulating electrical conductors with lead, &c. (Price 8d.)

The Patent Office has issued a notice to the effect that the official journal will in future be published weekly (on Saturdays) instead of bi-weekly as heretofore. Various alterations will at the same time be made in the "name" and "subject-matter" indexes; five indexes hitherto published will now cease to appear. The effect of these changes is that in future our weekly record of "Applications for Patents" will only be brought down to the Friday previous to the date of publication.

COMPANIES' MEETINGS & REPORTS.

International Cable Company (Limited).

The first annual general meeting of this Company was held at the offices, 34, Nicholas-lane, E.C., on Thursday, the 29th ult., under the presidency of Mr. W. J. Thompson.

The SECRETARY having read the notice convening the meeting,

The CHAIRMAN said: I appear before you as the Chairman of a Company which had a very warm reception at its start. We were quite prepared for opposition, as the many supporters of the existing companies were sure not to be friendly to our scheme, and certain parties thought themselves justified in casting ridicule upon it in the press; but having been engaged in this project now myself some considerable time, I must acknowledge the courtesy which I have experienced from all concerned in it, and though some people have made strong remarks they never cast any reflection on the directorate, and I may even go further and say that had they looked through other coloured glasses their verdict would have been with us. There is only one matter that I would further mention on this subject, and that is that some reference should be made to a remarkable letter which I think damaged this Company most seriously, and even at this time I cannot realise what the writer intended, or whether he really weighed in his mind what would be the effect of his words. The letter damaged this scheme; but you will hardly credit it, that the writer was at that time a Director, if not the Chairman, of a syndicate anxious to promote this scheme. We shall now ask your opinion as to what you wish us to do in this matter in future. We hold the opinion that the proprietor of a single share in the Company is as much entitled to his opinion as the holder of 100 shares. Had we studied our own ease and comfort we should have retired as soon as we found the public held back. We had large promises from Liverpool and Glasgow, which failed; but as there were large subscriptions from parties professedly anxious to see the scheme carried through, the Directors felt they should not resign as long as there was any appearance of success. They determined, however, that unless they could be satisfied that there were sufficient funds to carry out the scheme in its entirety, they would not risk the money of the subscribers, although there were frequent requests to commence. Certain foreign subscriptions proving doubtful was another reason for over caution. Your Directors have worked at their own personal cost, and hoped to the last, and our hope has not been abandoned. The promoters, on their part, met the different position most frankly, and consented to forego half their claims. A member of the Board offered at his own cost to put himself in communication with his friends in Paris. He went over, bringing the scheme to the notice of his friends. When there he made an arrangement with Count Dillon, and after this he went over at the request of the Board to Portugal and saw his Excellency Señor Aguilar, late Minister of Public Works, and obtained an important extension of the contract for the concession from twenty to forty years. There were minor concessions, and I may say you cannot too much thank him, though he requests that his name may not be mentioned. It will also be in the recollection of some of you that the British Government invited tenders for a

Digitized by Google

cable from Halifax to the Bermudas. As this was part of our scheme and would have been a key to our cables, to which we felt we might look, we entered into negotiations on the subject, and we have every reason to believe that if the British Government had not subsequently determined to defer the tender it would have been given to this Company. Had it been so we should have been in a position to lay down our cable. However, the thing is not entirely dropped. An official from the General Post Office called last week on Mr. S. Thompson to know if the scheme was going on. If we had succeeded in this, we could have gone on and found funds sufficient for carrying out the entire scheme. Well, we have also had communications from America and Spain to work with the Company, but until the main question is settled we feel it would be needlessly taking up time to consider these questions. At the present moment, the increased cost of copper is unfavourable; but, on the other hand, there seems to be less desire on the part of the existing companies to continue the war of rates. Well, you must decide as shareholders what to do. Our position as Directors has been anomalous. We always desired to go on if we could, and fairly and honourably. If the shareholders wish us to continue in office, I think we shall be willing to remain for six months. If, on the other hand, you come to the conclusion to close operations, we shall be prepared to resign and give the seven days' legal notice for a meeting. We have the money subscribed lying at the bank at seven days' call, where it has been since we received it—excepting something less than £600 which have been required for expenses of office, secretary, &c. The Board make no charge, and as we have nothing more to add, I shall now be happy to hear your views.

Mr. Surén said it would be important to know how much money had been subscribed and how much paid in.

Mr. Fox replied that 21,000 shares had been applied for, and £8,344 paid on application, and £811 on allotment.

Mr. Surén asked how much per cent. the expenses would be on the capital paid in.

Mr. Fox: About 10 per cent.

Mr. Surén: Well, I think the sooner we wind up the better, and I move that the Company be wound up.

Mr. Dain: I second that. I never had a notice of the first meeting.

Mr. Sydney Thompson (the solicitor), said the first Directors were the shareholders, and they appointed the present Directors.

Mr. Dain: Perhaps you will tell us if there has been any other meeting of the shareholders?

Mr. Thompson: No, there has not.

The Chairman: There has been no change on the Board, except that Lord Brabourne has retired and Señor Aguilar has died.

Mr. Holroyd said he had a considerable sum at stake in this Company, and proposed that it should not be wound up. From his information about it he did not think that would be a proper course, and he did not see why it should not be carried on to a successful issue.

Captain Wood seconded the amendment that the Company be not wound up, adding that he did so on the understanding that the present Board should remain in office. He was sure the shareholders would loyally support them in every way. The remarks of the Chairman in regard to the concession from the British Government were very appropriate, though probably it would not be wise to disclose all that took place. In the case of the company going into liquidation there would inevitably be heavy expenses both in litigation and liquidation, and probably, instead of getting 90 per cent., they would only get 10 per cent. returned. In regard to the concession, if they put on a bold front to the Government, he believed they would get it.

Mr. Gribbon spoke in support of the amendment. He was strongly interested in the Company, and thought if the present Board remained in office another six months, there was every prospect of bringing it to a successful issue. With a little more patience, the Company might be made a success.

Mr. Pope said if any information could be given to the meeting which would lead to unanimity it would be an advantage. It seemed to him an absurdity, seeing that they had a concession from the Portuguese Government for 40 years that they should wish to wind up. He supported the amendment.

Mr. Surén said his idea was to save all they could, and he did not see that there need be any litigation.

The Chairman: We take it as your decided opinion that the Company should be wound up.

M. De Ricci: Gentlemen, by your kind permission I wish to testify to the wonderful way in which our Chairman has worked, and, in answer to the very proper question put by Mr. Surén as to the amount that would be returned to you, I desire to say that the sum mentioned by the Chairman does not anything like represent what has been actually spent in the matter. I myself have spent more than half of that. I should be glad to be relieved of the responsibility of bringing this matter to a satisfactory issue. Whilst some have their thousands in it I have only £500. We have already achieved considerable results, and if you think it advisable we will still persevere, and perhaps it might desirable to adjourn for a short period.

The Chairman: Before I ask you to vote, there has been one point referred to as to the possibility of litigation. That is a point I have not taken into consideration. When certain gentlemen subscribed for the concessions, we had guarantees that they would not call for the return of that money. How the law would affect us I do not know. I cannot add more. I will now put the amendment that the International Cable Company shall not be wound up.

Nine voted for the amendment and five against.
